I would like to dedicate some lines to the people and institutions that have supported me during these years.

First, to the Computer Vision Center, the Universitat Autònoma de Barcelona, the Personal Investigador en Formació grant, the Spanish Government (projects TRA2007-62526/AUT, TRA2010-21371-C03-01, TRA2011-29454-C03-01, TIN2011-29494-C03-02 and Consolider Ingenio 2010: MIPRCV (CSD200700018)) and the Catalan Generalitat (project CTP-2008ITT00001).

I would like to thank the members of the tribunal, Dr. M. Enzweiler, Dr. J. González and Dr. J.A. Rodríguez, and the European mention evaluators Prof. Dr. Theo Gevers and Dr. A. D. Bagdanov. I also want to thank the anonymous journal and conference reviewers for their enriching comments during my thesis.

To the members of Davantis that introduced me into the research of Computer Vision always with a practical point of view in mind: J. Lluís, X. Miralles, M. Balcells, J. Pagès, M. Blasco, R. Esquius, P. Cunill and J. Capdevila.

My sincere thanks to Dr. D. Gavrila that gave me the opportunity of spending my internship at Daimler AG where I have learnt so much and the great people I met there: Dr. U. Franke, Dr. U. Kressel, Dr. M. Enzweiler, Dr. K. Keller, N. Schneider, F. Flohr and F. Erbs.

During my Ph.D. I was fortunate to have several collaborations. I would like to thank J. Marín, J. Xu, S. Ramos, M. Rao, Y. Socarrás, and D. Gerónimo for their good collaborations in research for enriching the quality of the work. Specially to J. Marín who shared with me this long trip since the first day, for his continued support at good and bad times, the long nights at the CVC and H3, the absurd jokes and friendship over these years. Also to the people involved in the ADAS car project: F. Lumbreras, G. Ros, S. Ramos, J. Xu and H. Piulachs.

To all the Computer Vision Center fellows but specially to Prof. Dr. J. Villanueva, Dr. J. Lladós and Dr. M. Vanrell. To the administrative staff that had the patience to support my extensive requirements, especially to C. Pérez. To the technical staff specially to M. Paz and J. Masoliver. To all my friends from the CVC, especially, to the ones that started this Ph.D. with me: J. Marín, J. C. Rubio, J.M. Gonfaus, J. Bernal, with whom I have shared so many interesting talks, coffees, parties and now I consider part of my best friends. To my friend G. Ros that since the first moment started with me to involve the ADAS members in the reading group, Eco- Driver project, etc. To S. Ramos a brand new member of the ADAS group that I already consider one of my best friends because he is always laughing, disposed to
collaborate, help others, create new projects and he thinks so big. Also, thanks for his extensive help reviewing this Thesis. Finally, to the remaining members of the ADAS group: Dr. A. Sappa, Dr. J. Serrat, Dr. J.M. Álvarez and A. González.

I am truly indebted and thankful to my advisor, Dr. A. M. López. Thanks for the invested time, the extensive writing, the support, the advices and even convincing me to quit smoking. I consider him one of the best persons I have ever met and I admire him. Thanks for the support and guidance he showed me throughout my dissertation writing. I am sure it would have not been possible without his help. I would like also to thank to my co-advisor Dr. D. Ponsa.

I ask for excuses to all my Barceloneta friends, ”La Familia”, because I didn’t care to much about them these last years. Of course, to J. Sobrino, my closest friend since I came to Barcelona. With her I have grown as a person and with her I have shared all the good and bad moments. She makes me laugh as nobody, with her there are no secrets and her friendship is priceless. I don’t forget my dear English teacher and friend Elena who always encouraged me to go further. I will be always in debt with her because she convinced me to start this Ph.D. Finally I want to acknowledge to my family in my own language:

Tener una familia como vosotros significa mucho para mí. Sois vosotros los que habéis formado el David que hoy existe. Nunca podré agradecer el apoyo que me habéis dado, ahora y siempre, estando a mi lado sin esperar nada a cambio. Gracias por cariño que me brindáis y la amplitud de miras que me habéis inculcado sin la cual, seguramente, no habría llegado a estar donde estoy.

Finalmente, quiero también agradecer por su comprensión y confianza a la persona que se ha ganado mi cariño, admiración y respeto. A una persona, de la que no diré su nombre, pero que sabrá quién es.

Miro con ilusión al futuro y a pesar de las dudas que se me plantean, cualquiera que sea el camino que escoja pasará por vosotros.
Abstract

Pedestrian detection is of paramount interest for many applications, e.g. Advanced Driver Assistance Systems, Intelligent Video Surveillance and Multimedia systems. Most promising pedestrian detectors rely on appearance-based classifiers trained with annotated data. However, the required annotation step represents an intensive and subjective task for humans, what makes worth to minimize their intervention in this process by using computational tools like realistic virtual worlds. The reason to use these kind of tools relies in the fact that they allow the automatic generation of precise and rich annotations of visual information. Nevertheless, the use of this kind of data comes with the following question: can a pedestrian appearance model learnt with virtual-world data work successfully for pedestrian detection in real-world scenarios?. To answer this question, we conduct different experiments that suggest a positive answer. However, the pedestrian classifiers trained with virtual-world data can suffer the so called dataset shift problem as real-world based classifiers does. Accordingly, we have designed different domain adaptation techniques to face this problem, all of them integrated in a same framework (V-AYLA). We have explored different methods to train a domain adapted pedestrian classifiers by collecting a few pedestrian samples from the target domain (real world) and combining them with many samples of the source domain (virtual world). The extensive experiments we present show that pedestrian detectors developed within the V-AYLA framework do achieve domain adaptation. Ideally, we would like to adapt our system without any human intervention. Therefore, as a first proof of concept we also propose an unsupervised domain adaptation technique that avoids human intervention during the adaptation process. To the best of our knowledge, this Thesis work is the first demonstrating adaptation of virtual and real worlds for developing an object detector. Last but not least, we also assessed a different strategy to avoid the dataset shift that consists in collecting real-world samples and retrain with them in such a way that no bounding boxes of real-world pedestrians have to be provided. We show that the generated classifier is competitive with respect to the counterpart trained with samples collected by manually annotating pedestrian bounding boxes. The results presented on this Thesis not only end with a proposal for adapting a virtual-world pedestrian detector to the real world, but also it goes further by pointing out a new methodology that would allow the system to adapt to different situations, which we hope will provide the foundations for future research in this unexplored area.
Resumen

La detección de peatones es clave para muchas aplicaciones como asistencia al conductor, video vigilancia o multimedia. Los mejores detectores se basan en clasificadores basados en modelos de apariencia entrenados con ejemplos anotados. Sin embargo, el proceso de anotación es una tarea intensiva y subjetiva cuando es llevada a cabo por personas. Por ello, vale la pena minimizar la intervención humana en dicha tarea mediante el uso de herramientas computacionales como los mundos virtuales porque con ellos podemos obtener anotaciones variadas y precisas de forma rápida. Sin embargo, el uso de este tipo de datos genera la siguiente pregunta: ¿Es posible que un modelo de apariencia entrenado en un mundo virtual pueda funcionar de manera satisfactoria en el mundo real? Para responder esta pregunta, hemos realizado diferentes experimentos que sugieren que los clasificadores entrenados en el mundo virtual pueden ofrecer buenos resultados al aplicarse en ambientes del mundo real. Sin embargo, también se encontró que en algunos casos estos clasificadores se pueden ver afectados por el problema conocido como el cambio en la naturaleza de los datos, igual que ocurre con los clasificadores entrenados en el mundo real. En consecuencia, hemos diseñado un sistema de adaptación de dominio, V-AYLA, en el que hemos probado diferentes técnicas para recoger unos pocos ejemplos del mundo real y combinarlos con una gran cantidad de ejemplos del mundo virtual para entrenar un detector de peatones adaptado. V-AYLA ofrece la misma precisión de detección que un detector entrenado con anotaciones manuales y probado con imágenes reales del mismo dominio. Idealmente, nos gustaría que nuestro sistema se adaptase automáticamente sin necesidad de intervención humana. Por ello, a modo de demostración, proponemos utilizar técnicas de adaptación no supervisadas que permitan eliminar completamente la intervención humana del proceso de adaptación. Hasta donde sabemos, este es el primer trabajo que muestra que es posible desarrollar un detector de objetos en el mundo virtual y adaptarlo al mundo real. Finalmente, proponemos una estrategia diferente para evitar el problema del cambio en la naturaleza de los datos que consiste en recoger ejemplos en el mundo real y reentrenar solamente con ellos pero haciéndolo de tal modo que no se tengan que anotar peatones en el mundo real. El resultado de este clasificador es equivalente a otro entrenado con anotaciones obtenidas de forma manual. Los resultados presentados en esta tesis no se limitan a adaptar un detector de peatones virtuales al mundo real, sino que va más allá, mostrando una nueva metodología que permitiría a un sistema adaptarse a cualquier nueva situación y que sienta las bases para la investigación futura en este campo todavía sin explorar.
Resum

La detecció de vianants es clau per moltes aplicacions com els sistemes d’assistència al conductor, la videovigilància o els sistemes multimèdia. Els millors detectors es basen en classificadors basats en models d’aparença entrenats amb exemples anotats. No obstant, el procés d’anotació és un procés feixuc i subjectiu quan és realitzat per persones. Per això, val la pena minimitzar la intervenció humana en aquesta tasca mitjançant l’ús d’eines computacionals com són els mons virtuals ja que amb ells podem obtenir anotacions variades i precises de forma ràpida. No obstant, la utilització d’aquestes dades, ens planteja la següent qüestió: És possible que un model d’aparença entrenat en un món virtual puguí funcionar de manera satisfactòria en el món real? Per respondre aquesta pregunta, hem realitzat diferents experimentes que suggereixen que els classificadors entrenats en el món virtual poden oferir bons resultats al aplicarse en ambients del món real. Tot i això, també s’han trobat alguns casos en que els classificadors es poden veure afectats pel canvi en la naturalesa de les dades, de la mateixa manera que passa amb els classificadors entrenats en el món real. Com a conseqüència de tot plegat, hem dissenyat un sistema d’adaptació de domini, V-AYLA. En aquest sistema hem provat diferents tècniques per recollir exemples del món real i combinar-los amb una gran quantitat d’exemples del món virtual, per entrenar un detector de vianants adaptat. V-AYLA presenta la mateixa precisió que un detector entrenat amb anotacions manuals i comprovat amb imatges reals del mateix domini. Idealment, ens agradaria que el nostre sistema s’adaptés automàticament sense necessitat d’intervenció humana. Amb aquest objectiu, proposem utilitzar tècniques d’adaptació no supervisada que ens permetin eliminar completament la intervenció humana en el procés d’adaptació. Fins on tenim coneixement, aquest representa el primer treball que demostra que és possible desenvolupar un detector d’objectes en el món virtual i adaptar-lo al món real. Finalment, proposem una estratègia diferent per evitar el problema del canvi de naturalesa de dades que consisteix en agafar exemples del món real i re entrenar tan sols amb ells però fent-ho de manera que no calgui anotar els vianants en el món real. El resultat d’aquest classificador és equivalent a un altre entrenat amb milers d’anotacions manuals. Els resultats presentats en aquesta tesi no es limiten a adaptar un detector de vianants virtuals al món real, sinó que va més enllà, mostrant una nova metodologia que permetria a un sistema adaptar-se a qualsevol situació que estableix les bases per a la investigació futura en aquest camp encara sense explorar.

eCo-DRIVERS
Ecologic Cooperative Driver and Road Intelligent Visual Exploration for Route Safety, 2012-2014
Reducing traffic accidents is an automotive driving force of the European Commission (EC), which points out the development of advanced driver assistance systems (ADAS) as key to reduce them. Another EC driving force is environment. In this case, electric cars are a major contribution of the automotive industry. Deploying current market ADAS into electric cars presents a difficulty. Current systems based on radar/lidar which are technologies not well suited for electric cars (price, interferences).

The aim of eCo-DRIVERS project is to research technologies for bringing ADAS to urban oriented electric vehicles. Two are the major distinctive features of the proposal: (1) the use of vision as eco-sensor; and (2) to follow a driver-centric approach, i.e., rather than thinking in road and driver monitoring as working-alone ADAS, eCo-DRIVERS will make them to cooperate in order to assist the driver only when he/she really needs it, or in other words, working as actual co-drivers. Both things together build the concept of eco-driver.

This Thesis has been developed under this project and thanks to the previous projects that lead to this one.
Chapter 1

Introduction

Advanced Driver Assistance Systems (ADAS) aim to improve traffic safety by providing warnings and performing counteractive measures in dangerous situations. Pedestrian Protection Systems (PPS) try to avoid vehicle-to-pedestrian collisions by detecting the presence of pedestrians around the vehicle in order to warn the driver, perform braking actions, or perform evasive manoeuvres. In the PPS, the key component is a forward facing image acquisition and processing system able to detect pedestrians in real-time, as well as fulfilling a demanding tradeoff between misdetections and false alarms. The main challenge of a PPS is detecting the pedestrians because they present a very high appearance variability. They can wear different clothes, change pose, carry different objects, and have a considerable range of sizes. Moreover, they have to be detected in urban scenarios with cluttered background, under a wide range of weather and illumination conditions, from different viewpoints and can be partially occluded. Accordingly, as the comprehensive state-of-the-art reviews in [29, 32, 43, 49, 56, 116] reveal, research on image-based pedestrian detection for PPS has been a very relevant topic in the computer vision community during the last decade.

The goal of a pedestrian detector is to find the pedestrians present in a given video (i.e. framing each one with a bounding box). The most widespread pedestrian detection framework consists of several stages [49]: (1) selection of candidates (image windows) to be classified as containing a pedestrian or not, (2) the classification of such windows, and (3) non-maximum suppression process to remove multiple detections. As we work with videos a (4) tracking stage is also used to remove spurious detections, improving the candidate selection process and deriving information like the motion direction of each pedestrian. All these stages are quite relevant and can contribute on their own to achieve a reliable pedestrian detector in terms of processing time and detection performance. However, since the number of candidates per image runs from thousands to hundred of thousands, the classification stage is specially critical in such a pipeline. Accordingly, most of the work done on image-based pedestrian detection has been focused on the classification stage, i.e. given a candidate window
INTRODUCTION

decide if it contains a pedestrian or not.

The most promising pedestrian detectors rely on appearance-based classifiers learnt supervisely. The learning machine requires annotated examples and counterexamples for training, i.e. pedestrians and background. In this framework, having sufficient variability in the training set is decisive to learn classifiers able to generalize for unseen scenarios [22]. Unfortunately, obtaining the desired variability in the training data is not easy for pedestrian detection in the PPS context, since we are limited to the variability of the annotated video sequences recorded from a car. We can hypothesize that larger training sets are likely to have higher variability, which seems to be confirmed by the fact that classification performance tends to increase with the size of the training sets for some classifiers [3], including pedestrian classifiers [79]. However, while increasing the number of counterexamples is automatic and effective, having a large number of examples is expensive in the sense that many video sequences must be recorded on-board and a large amount of manual intervention is required in the annotation process. Moreover, just subjectively adding more examples does not guarantee higher variability, i.e. it can happen that the human annotator just adds pedestrians quite similar to the ones previously annotated. In fact, the same can happen for the images from which counterexamples are collected.

Hence, obtaining good annotated samples (pedestrians and background) is a relevant open issue for learning reliable pedestrian classifiers within the discriminative paradigm. The ideal scenario is to be able to engineer the variability of the samples at low human annotation cost. In the pedestrian detection literature we can find some examples. However, either the results were not good [16] or costly manual silhouette delineation was required [34]. In fact, having good annotated examples is an issue for object detection in general, as well as for category recognition, image classification and any other visual task involving discriminative machine learning. Thus, in the last years different web-based tools, as LabelMe [8] or Amazon Mechanical Turk (MTurk) [89], have been proposed for manually collecting annotated information from images. However, web-based annotation has different problems inherent to human workers whose solution still requires more research [108].

One of the contributions of this thesis is a new idea for collecting training annotations. We want to explore the synergies between modern Computer Graphics and Computer Vision in order to close the circle: the Computer Graphics community is modelling the real world by building increasingly realistic virtual worlds, therefore it comes up the question, can we now learn our models of interest in such controllable virtual worlds and use them successfully back in real world?. In this thesis we aim to answer a more specific question for the PPS context: Can a pedestrian appearance model learnt with virtual-world data work successfully for pedestrian detection in real-world scenarios?. In order to address this question, we capture images at virtual urban scenarios using a virtual camera installed in a virtual car forward facing the virtual road ahead. To acquire such virtual-world images, we use a realistic videogame to obtain pixel-wise annotations of the imaged pedestrians. Figure 3.1 illustrates the

---

1For instance, since manual annotation of images free of examples is cheap, bootstrapping or cascade methods can be applied to gather hard false positives and retrain
There are different options to implement the proposed paradigm. We can learn a holistic (full-body) pedestrian classifier using dense descriptors [29,32,116], or the pedestrian silhouette [26]. Analogously, we can learn a part-based pedestrian classifier with dense descriptors [36,78] (here we would not need to search for parts location during training, since we can know such locations thanks to the pixel-wise annotations), or using the pedestrian silhouette instead [72]. In all cases, different learning machines can be used as well. Thus, given such a large amount of possibilities, in [77] we just followed popular wisdoms that suggests starting from the beginning. In particular, using virtual pedestrians and background, we trained a holistic pedestrian classifier based on histograms of oriented gradients (HOG) and linear support vector machines (Lin-SVM) [24,25]. We tested such classifier in a dataset, made publicly available by Daimler AG [32] for pedestrian detection benchmarking in the PPS context. The obtained results were evaluated in a per-image basis and compared with the ones from a pedestrian classifier trained analogously but using real-world images. This comparison revealed that virtual and real-world based training give rise to similar classifiers. In this Thesis we present a more in depth analysis than in [77] by introducing new descriptors (LBP [119], ExtHaar [32,78,79,84,114,115], EOH [68]), new learning machines (Real-AdaBoost [96]) and new datasets (Daimler, INRIA, Caltech-Testing [29], ETH-0,1,2 [121], TUD-Brussels [121] and CVC02 [48]); all them used before in the context of pedestrian detection, so that we can better appreciate the results of employing virtual-world samples for training.

The results of our experiments show that the same accuracy can be obtained by training with real-world data than by using virtual-world one (without doing any special selection of such virtual data, i.e. just driving randomly for acquiring virtual-world images). This is a very encouraging result from the viewpoint of object detection in general. Nevertheless, not only good behavior is shared between virtual- and real-world based training, but also some undesired effects. For instance, let us assume that, with the purpose of learning a pedestrian classifier, we annotated thousands of pedestrians in images acquired with a given camera. Using such camera and the learned classifier we fulfil the requirements of our application (PPS, video-surveillance, etc.). Later we must use a different camera or we have to apply the classifier in another similar application/context but not equal. This variation can decrease the accuracy of our classifier because the probability distribution of the training data can be now much different than before with respect to the new testing data. This situation is usually referred to as the dataset shift problem [92] and it is receiving increasing attention in the Machine Learning community [10,11,76,90–92] due to its applications in areas as natural language processing, speech processing and brain-computer interfaces, to mention a few.

The dataset shift has been largely disregarded in Computer Vision, however, recently some authors have started to pay attention to this problem in the context of object recognition [13,100]. Coming back to the example, in fact, the best we can do is to annotate the images from the new camera and learn a new classifier [10]. However, doing such new annotations is a never ending expensive procedure. In order to
INTRODUCTION

reduce to the minimum new annotations, the scientific challenge consists in performing some sort of adaptation between the training and testing/application domains. Virtual-world images, although photo-realistic, come from a different eye than those acquired with a real camera. Thus, we inherit the dataset shift problem. Accordingly, our proposal of using virtual-world images for learning pedestrian classifiers is cast in a domain adaptation framework. In [112], we gave a step forward into this direction, however, only using INRIA dataset and HOG descriptors. In this thesis we propose other alternatives than in [112] for combining descriptors coming from real- and virtual-world samples. We term our new learning framework as Virtual-AYLA\(^2\), or just V-AYLA, which stands for Virtual-world Annotations Yet Learning Adaptively. We will see that V-AYLA will combine our virtual-world based samples with a relatively few real-world based ones to reach the desired performance.

Ideally, we would like to deploy our vision system in the scenario where it must operate without human intervention. Then, the system should self-learn how to distinguish the objects of interest. We are interested in exploring the self-training of a pedestrian detector for driver assistance systems. Our first approach to avoid manual labelling consisted in the use of samples coming from realistic computer graphics, so that their labels are automatically available. This would make possible the desired self-training of our pedestrian detector. In order to overcome the dataset shift, we also explore the use of unsupervised domain adaptation techniques that avoid human intervention during the adaptation process. In particular, we explore the use of the transductive SVM (T-SVM) learning algorithm in order to adapt virtual and real worlds for pedestrian detection. We combine our virtual-world based samples with some real-world based detections to reach the desired performance.

1.1 Objectives

In summary, this PhD dissertation progressively addresses the following questions:

- Can a pedestrian appearance model learnt with virtual-world data work successfully for pedestrian detection in real-world scenarios?
- Can we adapt the models learnt in virtual scenarios to the particularities of real ones?
- Can the learnt models automatically adapt to changing situations without human intervention?

Bringing light to the mentioned questions are the objectives of this PhD. In the long term, our goal is to build a pedestrian detection system learnt without human intervention that automatically adapts itself to the environment changes.

\(^2\)AYLA name wants to evoke the main character (a Cro-Magnon women) of the popular saga *Earth’s Children* by Jean M. Auel.
1.2 Contributions

Accordingly, in this Thesis we present a pedestrian detector with several novel points:

- We use photo-realistic virtual worlds to learn the appearance model, \textit{i.e.} using automatic annotations combined with different state-of-the-art descriptors and learning machines.

- In order to address the dataset shift problem, we perform domain adaptation techniques using together virtual- and real-world samples during training. These techniques can be applied to object detection in general. In fact, to the best of our knowledge, our preliminary work [112] is the first paper considering the dataset shift problem for developing an object detector.

- We propose an unsupervised domain adaptation method, \textit{i.e.} human intervention is not required.

- We propose an automatic method for annotating pedestrian bounding boxes with weak supervision.

1.3 Outline

The rest of the thesis is organized as follows. In Chapt. 2 we review the literature related to different aspects of our proposals. Chapt. 3 presents and discusses the results obtained by using different pedestrian detectors based on the traditional (passive) learning methodology, \textit{i.e.} assuming that training and testing domains are equal. This demonstrates that a pedestrian appearance model learnt at virtual scenarios can be successfully applied to real images. In Chapt. 4 we present the results obtained using the V-AYLA methodology. In Chapt. 5 we present unsupervised version of V-AYLA and an alternative to the domain adaptation strategy to create new datasets with low annotation effort. Finally, Chapt. 6 draws the main conclusions of the presented work. In addition, we include Appendix A for quick access to the notation used in the Thesis.
Cool World
Ralph Bakshi, film, 1992
Jack Deebs is a cartoonist who is due to be released from jail. His comic book *Cool World* describes a zany world populated by *doodles* (cartoon characters) and *noids* (humanoids). What Jack did not realize is that Cool World really does exist, and a *doodle* scientist has just perfected a machine which links Cool World with our world. Intrigued at seeing his creating come to life, Jack is nonetheless wary as he knows that not everything in Cool World is exactly friendly. (Source: Film Affinity)

In *Cool World*, there is a real world and a cool world, in the latter, real humans and cartoons live together. In this Thesis the virtual- and the real-world pedestrians are used together in the same joint space for training an adapted classifier that can successfully work in the real world.
Chapter 2

State of the art

In this chapter we review some works that are related to our proposal, thought only in partial aspects: pedestrian detection, collecting annotations, engineering examples, and performing domain adaptation. Indeed, to the best of our knowledge there is neither previous proposals for pedestrian detection in particular, nor for object detection in general, where annotations coming from a photo-realistic virtual world are used to learn an appearance classifier that must operate in a real-world detection task (except for our preliminary works in [77,112]). Specially if the virtual world is domain adapted to the real one.

2.1 Pedestrian detection

Pedestrian detection has produced a vast interest over the last years in the computer vision community. Thus, many techniques, models, features and general architectures have been proposed. There exist three recent good surveys in the literature [29,32,49] that perform an extensive review of the pedestrian detection literature. In this section we will just review the works related to the object detection stage of the pedestrian detection pipeline proposed in in [49] (Fig. 2.1). This module receives a set of Regions Of Interest (ROIs) to be classified as pedestrians or non-pedestrians. Among the different methods proposed in this stage we focus on the appearance based ones, which define a space of image features and then run a learning machine on examples to obtain a classifier.

Several learning machines have been used in the literature, but we can condensate the most important ones into three groups. Neural Networks (NN) [21] are a bio-inspired architectures based on layers of neurons that lead to a non-linear classifier. Support Vector Machine (SVM) [62] is a statistical method that finds a decision boundary by maximizing the margin between the different classes. Ensemble methods [65] builds a strong classifier by a combination of weak classifiers. SVM [62] and the AdaBoost variants [40] are clearly the most widely used in the state of the art.
Figure 2.1: The general module-based architecture in [49] covers the structure of most of the systems. It is composed by six modules: preprocessing, foreground segmentation, object classification, verification, tracking and application.

Several feature spaces or descriptors have been proposed in the literature as well. The simplest features were proposed by Gavrila et al. [45] which used grey scale image pixels with a NN-LRF [21] as a learning machine. Zao et al. [124] used image gradient magnitudes combined with a NN. Papageorgiou et al. [81] introduced the Haar wavelets features that compute the pixel difference between two rectangular areas in different configurations and can be seen as large scale derivatives; they used a SVM for the classification. Viola and Jones [115] proposed an extended set of Haar wavelets features combined with an AdaBoost cascade. Gerónimo et al. [46] combined the Edge Orientation Histograms (EOH) with Haar wavelets in an Real-AdaBoost, resulting a robust and fast pedestrian detector (See Fig. 2.3).

Dalal et al. [25] presented the Histogram of Oriented Gradients (HOG), a SIFT [41] inspired feature that combined with a SVM is the reference feature on the state-of-the-art of pedestrian detection and have been extended by several authors (See Fig. 2.3). For instance, Zhu et al. [125] proposed to speed up the computation by changing the SVM by an AdaBoost cascade as classifier and feature selector. Wang et al. [119] added to [25] a texture descriptor, the local binary pattern (LBP) and an occlusion handling approach. Maji et al. [75] proposed a simplified version of HOG features, the multi-level oriented edge energy features, that combined with a SVM with a fast approximation of the histogram intersection kernel (HIK-SVM). Walk et al. [116] extended the use of this HIK-SVM with a combination of HOG, color-self similarity histograms (CSS) and histograms of flow (HOF) features. Enzweiler et al. [33] present a multilevel Mixture-of-Experts approach to combine information from multiple features (i.e. HOG and LBP) and cues (i.e. shape, intensity, depth and flow) with MLP [21] and linear-SVM as expert classifiers. Tuzel et al. [110] propose a novel algorithm based on the covariance of several measures as features and LogitBoost and Riemannian manifolds to classify them.

The aforementioned references consider the pedestrians as a whole so they are called holistic model. Felzenszwalb et al. [37] present an approach based on Dalal’s HOG detector that consists of a representation of the whole pedestrian and several
2.1. Pedestrian detection

Figure 2.2: Top: HOG features. Bottom: LBP features.

representations of pedestrian parts (e.g. arms, torso, head, etc). This kind of models are called part-based. The training is done using latent SVM. It is currently one of the best methods for object detection and has been extended by several authors. For instance, Pedersoli et al. [86] proposed a coarse-to-fine approach to accelerate the detector, while Park et al. [85] extended it with a multi-scale approach to explicitly model pedestrians seen at different distances to the camera.

An extension of [115], the channel features, done by Dollar et al. [28] is recently attracting much attention because it can be fast computed thanks to the integral images and the Haar-like filters. They use cues based on orientation, colour and grayscale. They extended their work by boosting the speed of the previous system [27] by computing the feature responses at a given scale and approximating the feature responses at nearby scales. Then, they introduced the crosstalk cascade [29] where nearby detectors share information to improve the computational efficiency. Finally, Benenson et al. [12] proposed a system that works at more than 100 fps based on the ideas of these previous works. In particular, he proposed a combination of depth information coming from stixels [52] with a fast GPU feature computation and a cascade approach. Instead of using a multi-scale image pyramid they use a multi-scale classifier for a fixed number of scales. They follow the procedure of [27] to approximate nearby classifier scales in between the fixed ones.
Analysing the results of the different proposals, we realized that the most promising pedestrian detectors relay on robust local descriptors (i.e. HOG, LBP) in combination with an SVM (i.e. linear-SVM, HIK-SVM) or on integral features easy to compute (i.e. Haar, EOH, Color) in combination with an ensemble method (i.e. Ral-AdaBoost, Random Forest). On top of this, part-based models, multi-resolution models, occlusion handling are build.

2.2 Collecting annotations

Since having good annotated examples is being recognized as a core issue for many Computer Vision tasks requiring supervised learning, in the last years different web-based tools have been proposed for collecting them. A well known example is LabelMe [8] which allows human volunteers to localize image objects of a established class category by framing them with polygons (see Fig. 2.4). Nowadays, however, Amazon’s Mechanical Turk (MTurk) [89] probably centralizes the most powerful web-based annotation force (see Fig. 2.5). MTurk allows researchers to define human intelligence tasks (HITs: what and how) of different difficulty (e.g. visual annotation tasks involve from marking points of interest to drawing polygons) to be taken by human online workers (turkers) which are paid for their work. Thousands of annotations have been already collected by using LabelMe and MTurk. Cost free in the former case and at a relative low cost in the latter. Unfortunately, as it is argued in [108], where these web-based tools and others are analyzed, it is a fallacy to believe that, because good datasets are big, then they are good.

A key reason behind such fallacy is the human factor involved in the annotation task, which poses difficulties for achieving some desirable properties of training datasets, such as large variety, precision, suitability and representativeness [108]. For instance, in general, humans performing web-based annotation tasks are not vision experts and do not have a scientific motivation. The lack of expertise implies that such human annotators do not know what types of mistakes can be especially problematic for the posterior machine learning process, they do not know what to do in special situations that were not included in the annotation instructions, or they can just misunderstand such instructions [31]. The lack of scientific motivation makes necessary to offer some economic reguard (e.g. only for less than the 15% of U.S. and Indian turkers money is irrelevant [99]), but setting the appropriate one becomes a difficult issue [108]: for underpriced work, workers participate for entertainment or curiosity, while for overpriced work we can attract not very skilled workers; in both cases the quality of the annotations can suffer in terms of variety, suitability and representativeness (e.g. in order to increase the number of performed HITs per time unit, the turkers could focus on cases easy to annotate, thus, introducing an artificial bias) and precision (e.g. to increase HITs/time, the annotations could be less accurate since higher accuracy needs more time). In fact, to detect the presence of low quality annotations due to such reasons or even due to malicious workers, it is necessary to collect multiple annotations from the same image/object and assessing annotation quality from them [108]. Moreover, in the case of MTurk, we have a web-based tool
2.2. Collecting annotations

**Figure 2.3:** *Top:* Haar filters. Example of a filter with parameters \((x, y, w, h)\) with basic forms of the Extended Haar set and examples of filters that give high response in regions containing pedestrians. *Bottom:* EOH features. The feature is defined as the relation between two orientations of a region.

—that is not only focused on annotations for the Computer Vision scientific community, but for any type of HIT and employer. This introduces a competition among employers regarding the difficulty of the HIT and the cost, for us being a drawback the fact that annotations for Computer Vision tasks many times are quite time consuming. Altogether highlights the question of how to collect data on the internet as non-trivial, opening a new research area [108]; and, since human work is involved in it with the respective economic regard, ethical questions arise too [99].

In fact, since human beings do better a tasks if they are enjoying, some authors have posed the annotation of video sequences task as a web-based game [73, 74]. However, as argued in [108], designing an entertaining game with the main purpose
of collecting good annotations is difficult in itself.

Note that what we propose in this thesis is to use photo-realistic videogames that are designed for entertainment, not for doing annotations (though they could be easily adapted for that), *i.e.* we would rely on one of the most powerful industries of the world\(^1\) that will be generating and improving such virtual worlds anyway. It is true that while in \([73, 74]\) annotations are collected from real-world video sequences, we propose to use photo-realistic virtual worlds which, a priori, can pose more challenges. However, in addition to the human factor of any of such web-based tools, learning from annotations on real-world images does not avoid dataset shift.

Note that it is not only that some modern videogames, life simulators and animation films, are gaining photo-realism, but also the whole simulation pyramid for creating an artificial life is being considered: visual appearance (shape and photo-realism), kinematics, perception, behavior and cognition. For instance, see \([104]\) for the case of animating autonomous pedestrians in crowded scenarios. This means that from such virtual worlds we could collect an enormous amount of automatically annotated information in a totally controlled manner. In other words, we could obtain training sets of large scale, variety, precision, suitability and representativeness. Thinking in the needs of the Computer Vision community, given an image taken in a

\[^{1}\text{Videogame industry has not noticed current worldwide crisis: its incomes equal those of film and music industries together.}\]
Figure 2.5: MTurk annotation platform. https://www.mturk.com/

virtual world form a virtual camera, intuitively it seems that we could ask for different types of automatically generated annotations, for instance:

- Scene visual annotations (e.g. for image classification and category recognition): what type of objects are there inside the image, what type of image is it (e.g. indoor, countryside, urban).

- Object visual annotations (e.g. for object detection and image segmentation): where are the objects in the image (bounding box, silhouette, pixel-level annotation), which is its pose, where are their parts, identity the object along the time (tracks) and its imaged pixels (dense optical flow), even distance from the virtual camera to the object points corresponding to such imaged pixels (dense depth; e.g. in [55,70] 3D points from synthetic data are used to build 3D models of real objects), as well as inter-object visual relationships (e.g. occlusions).

- Non-visual annotations (e.g. for gaining robustness using non-visual cues and working in overall scene interpretation): sounds, what are we seeing in terms of natural language, what is the functionality of each object, how objects relate each other to fulfill a task, etc.

Note that the possibility of exploring and recording such virtual worlds does not only make possible to obtain the corresponding annotations, in fact, we can design a priori the storyboard to collect specifically desired annotations: viewpoint, illumination, appearance of the objects of interest (pose, texture, color, size), backgrounds, etc. It is true that some types of annotations would be quite precise (e.g. bounding boxes and silhouettes), while others may have some error inherent to the generative
model behind the virtual world \((e.g.\) pixel-wise annotations for dense optical flow). However, such errors could be estimated and taken into account, something difficult to do for human annotations due to subjectivity (in fact, it is not realistic to think in pixel-wise manual annotations for dense optical flow). Moreover, an additional benefit is that, given a virtual image, we could have all such types of annotations simultaneously, something difficult to achieve by relying on human annotations \((e.g.\) the HITs in MTurk are far more constrained in terms of required annotations).

Certainly, the considerations exposed so far point out web-based annotation tools as an exciting new field. However, exploring the synergies between modern Computer Animation and Computer Vision can be also another one. This thesis aims to motivate such approach. Indeed, so far we have just foreseen the advantages of using virtual worlds for obtaining good annotations. Obviously, the annotated information is then \textit{acquired} in a virtual world, which poses some doubts about its usefulness to learn models that must operate in the real world. For instance, let us imaging that we are developing a basic tracker. This tracker uses an appearance model for describing the objects to be tracked and a motion model for describing how they can move. A priori, the trajectories of virtual objects projected into a virtual camera can be expected to be useful for learning the parameters of the motion model. In fact, the equations that govern the motion of the virtual objects and the equations of the motion model to learn may be the same. However, regarding the appearance model of the objects the situation is not that clear a priori, after all human beings can distinguish between an image acquired in a virtual world from another acquired in the real one, at least in general. On the other hand, most people assisting to movies or playing videogames set in modern animated worlds would say that the scenes and lifelike characters are quite photo-realistic. In fact, is not only a matter of the overall appearance of objects and environment (silhouettes, pose, etc.), but also in terms of low-level features as texture, since involved Computer Graphics algorithms try to approach the power spectrum of real images \([88, 97, 98]\).

In fact, there are some works in the literature that explore the use of virtual worlds to study the complex relations of human behaviour. \([7]\) presents a framework to automatically generate synthetic image sequences by designing and simulating complex human behaviours in virtual environments. This framework is improved in \([38,39]\) creating an augmented reality framework to increase the complexity of image sequences used in segmentation, tracking and behaviour analysis in terms of occlusions and crowds, in a scalable and controllable manner. \([5, 6]\) exploits this framework to evaluate the performance of tracking algorithms. However these works do not use this virtual data for training a human detector, they use it for the evaluation of tracking and behaviour analysis systems. Also, they do not focus on the dataset shift problem.

As a matter of fact, the use of virtual scenarios and virtual reality for training and evaluating human capabilities is common nowadays (pilots, surgeons, etc.). Nevertheless, beyond human observers, the question is if to the \textit{eyes} of the appearance-based descriptors that Computer Vision algorithms use for their tasks, virtual-world appearance is sufficiently close to real-world one. Thus, since visual appearance is the primary source of information for Computer Vision algorithms, a central question is:
can we learn appearance models based on realistic virtual-world appearance and use them successfully in real-world images?. As first proof of concept, in this thesis we address the yet more specific instance of such question: can a pedestrian appearance model learnt in realistic virtual scenarios work successfully for pedestrian detection in real images?

2.3 Engineering examples

In the web-based annotation approach humans annotate the content of the images, but can not manipulate such context. If the images have not sufficient variability, the annotations can not add it. Thus, there have been proposed different techniques which are related to ours one in the sense of using an automatic procedure to generate the desired pedestrian examples.

In [16] synthesized examples for pedestrian detection in far infrared images (i.e. images capturing relative temperature) are used. In particular, a rough 3D pedestrian model encoding the morphology of a person is captured from different poses and viewpoints. The background is just roughly modelled since it is mainly dark in the used images. Each combination of pose and viewpoint constitutes a kind of grayscale template of human relative temperature. Then, instead of following a learning-by-examples approach to obtain a single model (classifier), a set of templates is used by a posterior pedestrian detection process based on template matching. However, the authors admit poor results, since it is difficult to handle variability due to different clothes, person size, more complex background and, in addition, computational time increases with the number of templates to be considered.

In [34] the set of examples is enlarged by transforming the shape of pedestrians (annotated in real images) as well as the texture of pedestrians and background (see Fig. 2.6). The pedestrian classifier is learnt by using a discriminative approach (NNs with LRFs, and SVM with Haar). Since these transformations encode a generative model, the overall approach is seen as a generative-discriminative learning paradigm. The generative-discriminative cycle is iterated several times in a way that new synthesized examples are added in each iteration by following a probabilistic selective sampling to avoid redundancy in the training set. The reported results show that this procedure provides classifiers of the same performance than when increasing the number of training examples with new manually annotated ones. However, much of the improvement comes from enlarging the training set by applying jittering to the pedestrian examples as well as by introducing more counterexamples. Notice that jittering does not involve synthesizing pedestrians since it only requires shifting them inside their framing window, i.e. it is introduced to gain certain degree of shift invariance in the learnt classifiers. Besides, for applying the different proposed transformations the overall pedestrian silhouette must be traced, which requires a manual annotation much more labor intensive than standard bounding box framing of pedestrians. In fact, obtaining manipulated good-looking images of people by performing holistic human body transformations is in itself an area of research, specially when video is
involved and thus temporal coherence is required [57].

In [2, 103] it is used a human renderer software called POSER, from Curious Labs, to randomly generate synthetic human poses for training an appearance-based human pose recovery system. In this case, these are close human views, usually from the knees up, and it must be assumed either that human detection has been performed before pose recovery, or that the camera is framing a human.

In [51] a pedestrian tracker for video surveillance (static camera) are designed and validated in controlled conditions set in realistic virtual scenarios. In [94] it is also present a virtual simulation environment based on the Pennsylvania Station in New York for testing a distributed video surveillance camera network. However, the photorealism is quite primitive compared to the videogame used in [51]. In these works the focus is on demonstrating the usefulness of such virtual scenarios for performance evaluation and engineering situations of interest. For instance, in [51] the tracking relies on a standard color-based mean-shift operating in the virtual scenarios during testing. In this thesis we want also to encourage the use of such virtual scenarios. In fact, as we will see, we use the same videogame than [51] to collect our virtual data. However, we go a step beyond because we want that our appearance-based detectors, learnt in virtual scenarios, can operate in real-world images.

### 2.4 Domain adaptation

We will formally define domain adaptation in Chapt. 4, but by now let us work with the intuition already introduced in Chapt. 1: if we learn an appearance model using images coming from a training camera and typical environment, but then we change to another testing camera or environment, then we can suffer the dataset shift.
2.4. Domain adaptation

problem, \textit{i.e.} the typical object poses can change, and the typical backgrounds, as well as the behavior of the descriptors in which the appearance model relies. In short, the probability distribution of the training domain may be different from the one of the testing domain regarding the descriptor space. If that is that case, some sort of domain adaptation is required.

Domain adaptation is a fundamental problem in machine learning but it only started receiving attention recently \cite{11, 14, 15, 19, 61, 90, 91, 101}, specially in computer vision applications \cite{13, 30, 50, 64, 100, 109}. Indeed, pedestrian detection is a field where adaptation methods have been already proposed \cite{83, 117, 118}. However, related fields, such as class imbalance \cite{58}, covariate shift \cite{105}, and sample selection bias \cite{54, 122} has a longer history. There are also some related problems as multi-task learning \cite{17}, active learning \cite{1, 106} and semi-supervised learning \cite{9, 93} that have been studied more extensively. For an extensive review of the related literature the reader may to the recent good surveys in the literature: one more general \cite{60}, other focused on computer vision applications \cite{9} and other on transfer learning \cite{82}.

As first proof of concept about how to perform domain adaptation for object detectors, in Chapt. 4 we will use so-called \textit{active learning} \cite{23}, \textit{augmented descriptor space} \cite{90}, a combination of both, and in Chapt. 5 a first attempt of unsupervised domain adaptation based on transductive-SVM \cite{63}. To put our work into context, we briefly summarize some works related to active learning and the use of the augmented descriptor space.

Aiming to minimize human annotation burden, in \cite{1} an active learning system called SEVILLE (SEmi-atomatic VIual LEarning) is used for developing a pedestrian detector. Starting by 215 randomly human-annotated pedestrians and sufficient background samples, it is constructed a pedestrian classifier using an AdaBoost cascade, where the weak rules are decision stumps based on one-dimensional descriptors referred as YEF (yet even faster). This classifier is applied to unseen videos and detections are presented to a \textit{human oracle} that must report if they correspond to actual pedestrians or to background (false positives). In fact, not all detections are presented to the oracle. First, there are examined only image windows that intersect a predefined horizon line. This reduces the application of the current classifier to around 170,000 windows. Then, from these windows, just those classified with a score falling into the \textit{ambiguity region} of the current classifier are passed to the oracle. Once a full video is processed, the new annotated samples together with the previous ones are used to retrain a new classifier, \textit{i.e.} the active learning follows a \textit{batch} scheme. The process is iterated with new videos until a desired performance is achieved.

In \cite{106} it is also used a similar active learning system, called ALVeRT (Active-Learning-based VEHicle Recognition and Tracking), to develop a vehicle detector based on Haar descriptors and a cascade-based AdaBoost learning machine. In this case, 7,500 examples are randomly human-annotated to obtain a first version of the vehicle detector (passive phase). Then, 10,000 more annotations are collected by the human oracle during the active phase.

In these two work, training and testing images are coming from the same camera.
Thus, active learning is not used as a domain adaptation solution but as a method for collecting most meaningful samples (*selective sampling*) while reducing the annotation burden of pedestrians and vehicles, respectively. Note that from this point of view, active learning is a kind of bootstrapping counterpart since only difficult examples (*i.e.* those in the ambiguity region of the classifiers) must be annotated by the human oracle. Following the same point of view, training and testing a pedestrian classifier in virtual worlds, we could automatically annotate difficult virtual pedestrians analogously to a bootstrapping process. In fact, such an approach is used in [34] for increasingly generating new synthetic samples, though, as we commented before, it turned out not to be too effective.

However, in this thesis, we are interested in assessing active learning as a method for domain adaptation. Thus, we will ask a human oracle to annotate some difficult pedestrians on real images, though the initial classifier is based in a large number of virtual samples. After, retraining is based on a descriptor space where some samples come from virtual world (most of them) and others from real world (some of them). We term as *cool world*\(^2\) such joint descriptor space.

Finally, just to mention that we got the idea of using the augmented descriptor space technique from [90], where it is applied to many different problems though no one of the Computer Vision field. However, recently this idea has also been applied to object recognition as in [13] where web-annotated images are used for training and Caltech256 dataset for testing; as well as in [100] to account for different lighting and resolution conditions between real cameras. In this thesis, we challenge augmented descriptor space for a detection task. Moreover, in [13, 100] the domains to be adapted are both based on real-world images, while here one of the domains correspond to virtual-world images (the adaptation being performed in the cool world). Additionally, the descriptors involved in our detection task are different than in [13, 100].

---

\(^2\) *Cool world* term is a tribute to the movie with that title. In it, there is a real world and a cool world, in the latter, real humans and cartoons live together.
Half-Life 2
Valve Corporation, videogame, 2004
Half-Life 2, the sequel to Half-Life, is a first-person shooter video game and a signature title in the Half-Life series. Developed by Valve Corporation, it was initially released on November 16, 2004, following a protracted five-year, $40 million development cycle, during which a substantial part of the project was leaked and distributed on the Internet.

The game was developed alongside Valve’s Steam software. It introduced the Source game engine and, because of Steam, was the first single-player video game to require online product activation.

Like its predecessor, Half-Life 2 was met with near-unanimous critical acclaim. It was praised for its advanced physics, animation, sound, AI, graphics, and narrative. The game won 39 ”Game of the Year” awards; some publications named it ”Game of the Decade”. It won the title of ”Game Of The Decade” at the 2012 Spike Video Game Awards. Half-Life 2 has sold over 12 million copies making it a bestselling PC game.

(Source: Valve corporation)

In this Thesis we create a virtual city using the Half Life 2 game engine where we can drive with a virtual car to acquire pedestrian images. With these images we can train a system able to detect pedestrians in the real world.
Chapter 3

Learning appearance in virtual scenarios

Detecting pedestrians in images is a key functionality to avoid vehicle-to-pedestrian collisions. The most promising detectors rely on appearance-based pedestrian classifiers trained with labelled samples. This chapter addresses the following question: Can a pedestrian appearance model learnt with virtual-world data work successfully for pedestrian detection in real-world scenarios? (Fig. 3.1). Our experiments suggest a positive answer, which is a new and relevant conclusion for research in pedestrian detection. More specifically, we record training sequences in virtual scenarios and then appearance-based pedestrian classifiers are learnt using HOG and LBP with linear SVM, as well as Haar and EOH with Real AdaBoost. We test such classifiers in several publicly available datasets: INRIA, Daimler, Caltech, CVC02, TUD and ETH-0,1,2. Each datasets provide real-world images taken from different sources like personal photo albums or sequences acquired from a moving vehicle. The obtained results are compared with the ones given by the counterpart classifiers learnt using samples coming from real images. The comparison reveals that, although virtual samples were not specially selected, both virtual and real world based training give rise to classifiers of similar accuracy in some cases while there is a gap for others.

3.1 Introduction

The most promising pedestrian detection methods rely on appearance-based pedestrian classifiers learnt from labelled samples, i.e. examples (pedestrians) and counterexamples (background). Having sufficient variability in the sets of examples and counterexamples is decisive to train classifiers able to generalize properly [22]. Unfortunately, obtaining the desired variability in such sets is not easy for pedestrian detection since we cannot control the real world while recording video sequences. We can hypothesize that larger training sets are likely to have higher variability, which
seems to be confirmed by the fact that classification performance tends to increase with the size of the training sets in general [3] and for some pedestrian classifiers [79] in particular. However, while increasing the number of counterexamples is automatic and effective (e.g. bootstrapping or cascade methods can be applied to gather false positives and retrain), having a large number of labelled examples is expensive in the sense that many video sequences must be recorded on-board and a large amount of manual intervention is required. Moreover, just subjectively adding more examples does not guarantee higher variability, i.e. it can happen that we are just adding...
3.1. Introduction

Figure 3.2: Virtual image with corresponding automatically generated pixel-wise groundtruth for pedestrians.

The reviewed proposals in Chapt. 2 are appealing in the sense that if we are able to use a set of automatically generated examples for learning, then we will have an easier control of its variability and cardinality and avoid human labelling for the learning phase. The central idea we propose in this chapter is the following. Rather than using rough morphological models or synthesized real examples, we propose to explore the synergies between modern Computer Animation and Computer Vision in order to close the circle: the Computer Animation community has modelled real world by building increasingly realistic virtual worlds, especially in the field of video games, thus, can we now learn our models of interest in such virtual worlds and use them successfully back in real world? In this chapter we focus the challenge in the appearance of pedestrians captured by a camera working at the visible spectrum (Fig. 3.1).

In the followin we present an in depth analysis of our proposal by testing several descriptors, learning machines and datasets used in the context of pedestrian detection, so that we can better appreciate the effect of employing virtual worlds for learning. Training with Lin-SVM we assess the behaviour of HOG, and of cell-structured local binary patterns (LBP) [119]. Since HOG is more related to overall shape and LBP to texture, following [119] we combine HOG and LBP too. We evaluate HOG and LBP separately instead of only considering the combination HOG+LBP, because we aim to assess the behaviour of such single descriptors when transferred from virtual-world images to real-world ones; moreover they are used separately as experts by some mixture-of-experts pedestrian classifiers [33]. In fact, HOG alone is the key descriptor of state-of-the-art part-based object detection [36], as well as in combination with LBP [123]. Additionally, we will study a different set of descriptors that are also popular for pedestrian detection and remain competitive: the extended Haar wavelets (ExtHaar) [32, 71, 79, 115] and the edge orientation histograms (EOH) introduced in [68], as well as the combination of both [20, 47, 48]. Due to their high
dimensionality an AdaBoost variant is usually employed as learning machine with these descriptors. We choose Real-AdaBoost [96] since it gave us very good results in other object detection tasks of the driver assistance context [4, 87].

The experiments we conduct here suggest a positive answer to the previous question, which we think is a new and relevant result for research in pedestrian detection. The classifiers trained on virtual data are evaluated in a per-image basis and compared with the classifiers trained using real datasets. The comparison reveals that virtual-based training and real-based one give rise to similar classifiers in some cases while there is a gap for others. Furthermore, given that at this time we do not fine tune virtual training sets, the obtained outcome opens the possibility of a more custom design of these sets to obtain better classifiers, e.g. following active learning approaches as proposed in [34, 37] or developing our own virtual world.

The remainder of the chapter is organized as follows. Section 3.2 details the datasets, pedestrian detector stages, and evaluation methodology, that will be consistent for the remaining of the thesis. Section 3.3 details the conducted experiments while Sect. 3.4 presents the results and corresponding analysis. Moreover, Sect. 3.5 present additional experiments in terms of extra datasets and features. Finally, Sect. 3.6 summarizes the conclusions and future work.

3.2 Experimental settings

3.2.1 Datasets

The lack of publicly available large datasets for pedestrian detection in the ADAS context has been a recurrent problem for years [28, 32, 49]. The INRIA dataset [25] has been the most widely used for pedestrian detection, however, it contains photographic pictures in which people is mainly close to the camera and on focus. Moreover, there are backgrounds that do not correspond to urban scenarios, which are the most interesting and difficult ones for detecting pedestrians from a vehicle. Fortunately, two more adapted datasets for the ADAS context have been made publicly available recently. One of them is presented by Caltech [28] and the other one by Daimler AG [32]. Also there exist other datasets that are also commonly used in the literature like, ETH-0,1,2 [121], TUD [121] and CVC02 [48]. Fig. 3.3 shows some examples of each dataset.

In order to illustrate our proposal, we focus on two real-world datasets and our virtual-world one. As generic real-world dataset we have chosen the INRIA (I) one [24] since it is very well-known and it is still used to evaluate pedestrian detection references [20, 29, 116, 119]. It contains color images of different resolution (320×240 pix, 1280×960 pix, etc.) with persons photographed in different scenarios (urban, nature, indoor). As real-world dataset for driving assistance we use the one of the automotive company Daimler (D) [32], which contains urban scenes imaged by a 640×480 pix monochrome on-board camera at different day times. Both INRIA and Daimler datasets are found divided into training and testing sets. Our virtual-world
3.2. Experimental settings

**Figure 3.3:** Some of the samples used to train/test from real-world images (Daimler, INRIA, CVC02, TUD, ETH and Caltech) and virtual-world ones.

dataset ($\mathcal{V}$) is generated with Half Life 2 videogame as detailed in [77]. However, for this work we have generated new virtual-world color images containing higher quality textures with anisotropic interpolation, more sequences to extract pedestrians, anti-aliased pedestrian-free images, and much more variability in urban furniture, asphalts, pavement, buildings, trees, pedestrians, etc. Emulating Daimler, virtual-world images are of $640 \times 480$ pix resolution. We use this virtual data only for training.

INRIA data includes a set of training images, $\mathcal{S}_{tr}^{+}$, with the BB annotation of 1,208 pedestrians. Daimler training set contains 15,660 cropped pedestrians. The images containing them are not available (i.e. there is not a $\mathcal{S}_{D}^{tr+}$). These pedestrians were generated from 3,915 original annotations by jittering and mirroring. At virtual world we can acquire a set of images, $\mathcal{S}_{V}^{tr+}$, of any desired cardinality, with annotated pedestrians.

Training with more pedestrians could lead to better classifiers a priori. For avoiding such a potential effect, the cardinality of the smallest pedestrian training set (i.e.
the 1,208 of INRIA) is used in our experiments. In the case of Daimler, firstly we grouped jittered and mirrored versions of the same annotation, obtaining 3,915 groups out of the 15,660 provided pedestrians. Secondly, we selected 1,208 cropped pedestrians by randomly taking either zero or one per group. In the case of the virtual-world pedestrians, we selected 1,208 randomly. In all cases, we generate a copy of each pedestrian by vertical mirroring. Thus, the number of available pedestrians for training with each dataset is 2,416. Hereinafter, we term as $T_{tr}^{+}$, $T_{tr}^{-}$ and $T_{V}^{tr}$ these sets (of the same cardinality) from INRIA, Daimler, and virtual world, respectively.

Additionally, each dataset includes pedestrian-free images ($\mathcal{I}_{tr}^{-}$, $\mathcal{I}_{tr}^{-}$, $\mathcal{I}_{D}^{-}$) from which gathering counterexamples for training. INRIA provides 1,218 of such images and Daimler 6,744. As with pedestrians, we limit the number of pedestrian-free images to 1,218 per dataset. Thus, we use all the INRIA ones, for Daimler we randomly choose 1,218 out of the 6,744 available. For the virtual-world case, we drove through uninhabited virtual cities, collecting 6,831 pedestrian-free images, from which we randomly selected 1,218. The final number of used counterexamples from each dataset depends on bootstrapping (Sect. 3.2.3). Hereinafter, we note such sets of counterexamples from INRIA, Daimler and virtual world as $T_{tr}^{I}$, $T_{D}^{I}$ and $T_{V}^{I}$, respectively. Accordingly, we define the training settings $T_{tr}^{X} = \{T_{tr}^{+}, T_{tr}^{-}\}$, $X \in \{D, I, V\}$.

We use the complete INRIA testing dataset ($T_{tr}^{I}$) consisting of 563 pedestrians in 288 frames and 453 pedestrian-free images. As Daimler testing dataset ($T_{D}^{t}$) we use 976 mandatory frames, i.e. frames containing at least one fully visible pedestrian taller than 72 pixels. Daimler defines non-mandatory pedestrians as those either occluded, not upright, or smaller than 72 pix high, the rest are considered mandatory and correspond to pedestrians in the range $[1.5m, 25m]$ away from the vehicle. There are 1,193 mandatory pedestrians in $T_{D}^{t}$. Sets $T_{tr}^{I}$ and $T_{D}^{t}$ are complementary in several aspects. $T_{tr}^{I}$ images are hand-shotted color photos, while $T_{D}^{t}$ contains on-board monochrome video frames. This turns out in complementary resolutions of the pedestrians to be detected as can be seen in Fig. 3.4. Moreover, $T_{D}^{t}$ only contains urban scenes, while in $T_{tr}^{I}$ we found scenarios like city (916 pedestrians), beach (50),

![Figure 3.4: Pedestrian height distributions of $T_{tr}^{I}$ and $T_{D}^{t}$.](image_url)
3.2. Experimental settings

countryside (138), indoor (87) and snow (17).

3.2.2 Pedestrian Detector

In order to detect pedestrians, we scan a given image for obtaining windows to be classified as containing a pedestrian (positives) or not (negatives) by a learnt classifier. Since multiple positives can be due to a single pedestrian, we must select the best one, i.e. the window detecting the pedestrian. Figure 3.1 illustrates the idea for a pedestrian classifier learnt with virtual-world data. In the following we briefly review the employed scanning and selection procedures.

Our scanning approach is based on pyramidal sliding window [24]. It consists in constructing a pyramid of scaled images, for the range of scales in which we want to detect the pedestrians. The bottom of the pyramid (higher resolution) is the original image, while the top is limited by the size of the so-called canonical window (CW, Sect. 3.2.3). At the pyramid level \( i \in \{0, 1, \ldots \} \), the image size is \( \lceil d_x/s_p^i \rceil \times \lceil d_y/s_p^i \rceil \), being \( d_x \times d_y \) the dimension of the original image \((i = 0)\), and \( s_p \) a provided parameter. Opposite to [24], for building levels of lower resolution we perform down-sampling by using standard bilinear interpolation with anti-aliasing, as in [37]. Then, a fixed window of the CW size scans each pyramid level according to strides \( s_x \) and \( s_y \), in \( x \) and \( y \) axes, resp. We experimentally found that \( \langle s_x, s_y, s_p \rangle := \langle 8, 8, 1.2 \rangle \) is a good tradeoff between final detection performance and processing time. This procedure has some differences regarding usual pedestrian detectors based in the descriptors tested in this chapter. We have experimentally seen that, in general, the pyramid with anti-aliasing boosts the performance of the pedestrian detectors based on LBP and HOG descriptors.

The CW of a classifier trained with \( T_{tr}^X \) is larger than with \( T_{tr}^D \) (Sect. 3.2.3). Then, if we train with \( T_{tr}^D \) and test with \( T_{tt}^I \), we down-scale the testing images using bilinear interpolation with anti-aliasing. If we train with \( T_{tr}^I \) and test with \( T_{tr}^D \), following [121] advice we up-scale the testing images using bilinear interpolation. \( T_{tr}^V \) can be adapted to any CW (Sect. 3.2.3).

As a result of the pyramidal sliding window, several overlapped positives at multiple scales and positions are usually found around the pedestrians. We apply non-maximum-suppression [66] to (ideally) provide one single detection per pedestrian.

3.2.3 Training process

In this section we focus on one of the most widespread [29,32,49,116] training methodology within the discriminative paradigm. We refer to the situation in which only randomly annotated training examples are used to learn a classifier. Sets \( T_{tr}^X \), \( X \in \{D, I, V\} \), are of such a type. We term this approach as passive.

Discriminative learning of a pedestrian classifier requires the computation of descriptors able to distinguish pedestrians from background. As we introduced in Sect.

3.1. HOG, LBP, ExtHaar and EOH are very well suited for this task. However, the current state of the art is mainly based on HOG and LBP, so, we will focus more on these two. For such descriptors being useful, a canonical size of pedestrian windows must be fixed. This CW size, \( w \times h \) pix, depends on the dataset and the descriptor.

In the case of INRIA, we have \( w \times h \equiv (32 + 2f) \times (96 + 2f) \), where \( f \) denotes the thickness (pix) of a background frame around the pedestrian (the so-called context). Thus, annotated pedestrians are scaled to 32 × 96 pix. Analogously, for Daimler \( w \times h \equiv (24 + 2f) \times (72 + 2f) \). For INRIA and HOG/LBP descriptors, \( f = 16 \) is of common use in the literature, e.g. this \( f \) gives rise to the traditional INRIA CW of 64 × 128 pix [25]. For Daimler and HOG/LBP, the usual value of \( f \) is \( f = 12 \), therefore, \( w \times h \equiv 48 \times 96 \) [32]

In the case of the virtual-world pedestrians, we just consider those larger than 32 × 96 pix. Then, when training classifiers for testing in \( T^{tr+}_{\mathcal{D}} \) we use \( w \times h \equiv (32 + 2f) \times (96 + 2f) \), while for testing in \( T^{tr+}_{\mathcal{I}} \) we use \( w \times h \equiv (24 + 2f) \times (72 + 2f) \). In both cases we use exactly the same pedestrian annotations for training, but in the case of Daimler we down-scale them more than in the case of INRIA. Hence, we actually have different \( T^{tr+}_{\mathcal{V}} \) sets. However, we avoid a more complex notation for making explicit the differences provided that we have clarified the situation. As it is done during testing (Sect. 3.2.2) down-scaling uses bilinear interpolation with anti-aliasing.

Collecting the counterexamples to form the \( T^{tr-}_{\mathcal{X}} \) sets, \( \mathcal{X} \in \{ \mathcal{D}, \mathcal{I}, \mathcal{V} \} \), involves two stages. In the first stage, for each example in \( T^{tr+}_{\mathcal{X}} \) we gather two counterexamples by randomly sampling the respective pedestrian-free images. For doing such a sampling, the pyramid of each pedestrian-free image is generated and then at random levels and positions two CWs are taken. Since the cardinality of \( T^{tr+}_{\mathcal{X}} \) is 2,416 and to form the initial \( T^{tr-}_{\mathcal{X}} \) we have 1,218 pedestrian-free images, we have approximately the same quantity of examples and counterexamples. In the second step, we follow a bootstrapping training methodology [25,32,116]. This means that with the initial \( T^{tr+}_{\mathcal{X}} \)
3.2. Experimental settings

and \( T^r_{tr} \) sets we train a classifier using the desired descriptors and learning machine. Then, the corresponding pedestrian detector is applied on the pedestrian-free training images to extract the so-called hard counterexamples, \textit{i.e.} false detections. All these new counterexamples are added to \( T^r_{tr} \) and, together with \( T^{r+}_{tr} \), the classifier is trained again. We keep this loop until the number of new hard counterexamples is smaller than 1% of the cardinality of current \( T^r_{tr} \) set. Following such a stopping rule of thumb and the initial 1:1 ratio between examples and counterexamples, we found that one bootstrapping step was sufficient in all the experiments. We forced more bootstrappings in different experiments to challenge the stopping criteria, but the results were basically the same because very few new hard counterexamples were collected. In [116] it is also recommended to follow a strategy such that almost all counterexamples are collected by the bootstrapping.

Table 3.1 summarizes the parameters used to compute such descriptors. HOG is computed using the parameters of the original proposal [25]. In the case of LBP, we introduce three improvements with respect to the approach in [119]. First, we use a threshold in the pixel comparisons, which increases the descriptor tolerance to noise. Second, we do not interpolate the pixels around the compared central one given that it distorts the texture and can impoverish the results. By doing so we could lose scale-invariance, but in our case it does not matter thanks to the image-pyramid. Third, we perform the computation directly in the luminance channel instead of separately computing the histograms in the three color channels, which reduces the computation time while maintaining the performance. As Lin-SVM implementation we use LibLinear [95], setting \( C = 0.01 \) and \( \text{bias} = 100 \).

3.2.4 Evaluation methodology

In order to evaluate the performance of the pedestrian detectors we reproduce the procedure proposed in [29]. This means that we use performance curves of \textit{miss rate vs false positives per image}. We focus on the range \( \text{FPPI}=10^{-1} \) to \( 10^{0} \) of such curves, where we provide the \textit{average miss rate} (AMR) by averaging its values taken at steps of 0.01. Accordingly, such an AMR is a sort of expected miss rate when having one false positive per five images. This is an interesting assessment point for our application area, \textit{i.e.} driver assistance, since such a FPPI can be highly reduced by a temporal coherence analysis. Besides, all annotated INRIA testing pedestrians and the mandatory ones of Daimler must be detected (Sect. 3.2.1).

The evaluation procedure described so far is rather standard. However, according to our daily working experience, even using a good \textit{bootstrapping} method [116] the AMR measure can vary from half to even one and a half points, up or down, due to some random choices during the training process. Of course, such a small variation does not convert a good detector in bad or the opposite. However, sometimes this is the performance difference among ranked detection algorithms [29]. Thus, it seems reasonable to rely on several training executions per experiment. Nevertheless, this may turn out in an enormous number of costly experiments. Therefore, in this chapter we have opted for repeating only the most representative experiments. Those are the
Table 3.2: Evaluation of virtual-world pedestrian detectors (HOG, LBP and HOG+LBP) over INRIA and Daimler datasets. AMR is shown in % for FPPI $\in [10^{-1}, 10^0]$. Bold values are the best comparing training sets $(T^t_X, X \in \{D, I, V\})$ for fixed descriptor, learning machine, and testing set $(T^t_R, R \in \{D, I\})$.

($\star$) Dalal et al. implementation [24].
($\circ$) Wang et al. implementation [119], without occlusion handling.
($\bullet$) Training with the 15,660 pedestrians.

Based on INRIA and Daimler datasets trained with HOG and LBP features. For each of these experiments we repeat the training-testing run five times, which is a moderate number of repetitions but, as we will see, it is sufficient to run different statistical tests that will validate our hypothesis of interest. Then, rather than presenting the AMR of a single train-test run, we present the average of five runs and the corresponding standard deviation.

3.3 Results

Table 3.2 shows the performance of the experiments HOG, LBP and HOG+LBP over the INRIA and Daimler datasets: 25 detectors we developed following passive training and evaluated according to Sect. 3.2.4. Figures 3.5 and 3.6 offer a visual insight by
3.4 Discussion

Experiments of table 3.2 sustain our claim that the performance of our pedestrian detectors is boosted by adding a pyramid with anti-aliasing and other improvements for the LBP. Our current HOG implementation gives better results for $\{T_{tr}, T_{tt}\}$ and $\{T_D^{tr}, T_D^{tt}\}$ than the original one [24] (used by us in [77,111]) due to the anti-aliasing in down-scaling operations. Also, our settings for LBP give better results for $\{T_I^{tr}, T_I^{tt}\}$

---

**Figure 3.5:** Evaluation of virtual-world pedestrian detectors (HOG and LBP) with INRIA and Daimler datasets.

plotting the performance curves. As each detector is trained and tested five times, for each detector, Table 3.2 shows the average AMR and its corresponding standard deviation, and Figures 3.5 and 3.6 plot average curves with their corresponding standard deviation intervals. Thus, these experiments involve 125 train-test runs.
Figure 3.6: Evaluation of virtual-world pedestrian detectors (HOG+LBP) with INRIA and Daimler datasets.
and \( \{T_{tr}^D, T_{tt}^D\} \) than the proposal in [119], thanks to the anti-aliasing and the pattern discretization threshold. When using HOG+LBP we obtain an improvement of almost 10 points for \( \{T_{tr}^I, T_{tt}^I\} \) and around 16 for \( \{T_{tr}^D, T_{tt}^D\} \), with respect to [119]. Note that the better the performance when training and testing within the real data, the higher the challenge to reach the same performance when training with virtual data and testing with real data.

We could expect that pedestrian detector trained in a video game could never be applied into the real world but, far from this, it performs fairly good. Table 3.2 reveals that the standard HOG/LinSVM pedestrian detector trained on virtual data and tested on Daimler dataset the performs exactly as its counterpart trained on Daimler training data. However, for INRIA there is a performance gap of 11 points. Even this is a considerable performance drop the virtual detector stills perform fairly well regarding the great challenge of training with virtual data. Nevertheless, using LBP features the performance gap is quite wider 10 points for Daimler and 15 for INRIA. Even that virtual detectors does not perform as well as real world ones they provide promising results.

Table 3.2 shows that using train and test sets of different sources (whether real or virtual) increases the AMR mean even 15 percentual points depending on the descriptor and dataset. This stands also when training and testing data come from different real world datasets. To assess this claim, we have checked the statistical significance of these results. For each descriptor, we consider all the detectors obtained by the different train-test runs using the two considered real-world training sets. Since we have tested such detectors on both real world test sets, by paring the obtained performances we can apply a paired Wilcoxon test [120]. The test reveals that for HOG, LBP and HOG+LBP testing and training with samples/images of the same dataset is better than using different datasets in the 99.9% of the cases (p-value = 0.001, being the null hypothesis that training and testing data are equal). The means of the improvement are 13.62, 10.35 and 10.73 AMR points for HOG, LBP and HOG+LBP, respectively.

We also argue that training with virtual-world data exhibits the same problem, but just as real-world data does. In order to support this claim, we have analysed if detectors trained with \( V \) data behave similarly to detectors trained with real-world data (using \( I \) and \( D \) datasets) when tested on a different real world dataset. In this case, since the compared virtual- and real-world-based detectors use different training data, all feasible pairings between their performances have to be taken into account and an unpaired Wilcoxon test (a.k.a Mann-Whitney U test [53]) must be applied. This test allows to conclude that when using \( I \) as testing data, detectors trained with \( V \) data provide better results than training with \( D \) data. This is true the 99.6% of the cases (one sided p-value = 0.004). The means of the improvement are 5.94, 10.89 and 8.85 AMR points for HOG, LBP and HOG+LBP respectively. When the testing dataset is \( D \), the analogous analysis reveals that training with \( V \) data is better for HOG than using \( I \) (10.62 points), while for LBP and HOG+LBP training with \( I \) data is better (9.46 and 2.18 points, respectively), with one-sided p-value = 0.004. Therefore, regarding the performance, the virtual-world data is comparable to
VIRTUAL SCENARIOS

a real-world one.

Usually there are several (possibly simultaneous) reasons giving this fact. For instance, with HOG, \( \{ T^{tr}, T^{tt} \} \) setting offers similar results to \( \{ T^{tr}_D, T^{tt}_D \} \) one, while \( \{ T^{tr}, T^{tt}_I \} \) results are much more distant from \( \{ T^{tr}_I, T^{tt}_I \} \), probably because our virtual-world data comes from urban scenes as Daimler data, but INRIA incorporates other scenarios. For LBP, however, \( \{ T^{tr}_V, T^{tt}_D \} \) results are much worse than \( \{ T^{tr}_D, T^{tt}_D \} \) ones. In fact, \( \{ T^{tr}_V, T^{tt}_D \} \) performance based on HOG is approximately 15 points better than the LBP one, while HOG and LBP show a difference of around 5 points for \( \{ T^{tr}_D, T^{tt}_I \} \). Thus, the textures of the virtual-world somehow differ more from Daimler images than the shape of the pedestrians. The best performance corresponds to combining HOG and LBP. In this case, for instance, \( \{ T^{tr}_V, T^{tt}_I \} \) setting is around 10 points worse than using \( \{ T^{tr}_I, T^{tt}_I \} \) one. This can be due to the fact that typical background and pose of virtual-world pedestrians do not include all INRIA cases (e.g. out-of-city pictures). The result for HOG+LBP and \( \{ T^{tr}_V, T^{tt}_D \} \) is approximately 2 points\(^1\) worse than for \( \{ T^{tr}_D, T^{tt}_D \} \), which could come from the pedestrians clothes (texture/LBP) rather than from pedestrian poses (shape/HOG).

3.5 Additional experiments

For complementing performance assessment, we extend our experiments in two ways: by adding more datasets and by adding more descriptors. We will follow the experimental settings explained in Sect. 3.2. However, as we have seen that the corresponding standard deviations seems to be stable and less than ±2 to alleviate the number of experiments we do not repeat each experiment.

3.5.1 Other datasets

To validate our results we will perform the experiments on the remaining datasets from Fig. 3.3: Caltech, ETH-0,1,2, TUD and CVC02. Next, we point the main characteristics of these datasets.

Caltech [29] is a popular pedestrian dataset. It contains color images of 640 × 480 pix resolution acquired from a vehicle driven through different urban scenarios at different day times. For training, in [29] it is used INRIA training data but we also use Caltech training data. In particular, from Caltech training videos we selected all the non-occluded pedestrians taller than 72 pix but avoiding the inclusion of the

\(^1\)The best \( \{ T^{tr}_V, T^{tt}_D \} \) for HOG+LBP does not correspond to the full set of Daimler pedestrian examples (15,660) but to our selected set (2,416 ones), i.e. examples without jittering. Since jittering neither add shape variability nor appearance provided that the size of the cells we use for HOG and LBP is bigger than the degree of jittering, it may be just introducing some overfitting. Note that in [32] pedestrian classifiers training is based on local receptive fields and neural networks (LRF/NN), thus, shift invariance must be explicitly introduced (e.g. using jittering).
3.5. Additional experiments

same pedestrian many times. This procedure outputs 790 pedestrians, thus, we have 1580 examples after mirroring. Moreover, to keep the same ratio between positive and negative training data than in previous experiments, we randomly choose 605 pedestrian-free Caltech training frames. We set the CW following INRIA settings, and we use image up-scaling during testing for detecting reasonable pedestrians (i.e. most representative ones [29]) taller than 50 pix but not reaching the 96 pix of the INRIA CW setting.

The ETH dataset [121] was recorded at a resolution of 640 × 480 pix resolution, using a stereo pair mounted on a children stroller. For our particular experiments, only the left images of each image-sequence are used. The ETH dataset contains three sub-sequences, representing three different scenarios, which are denoted as ETH0, ETH1 and ETH2. ETH1 corresponds to the 999 frame ”BAHNHOF” sequence, ETH1 are the 451 frame ”JELMOLI” sequence and ETH1 the 354 frame ”SUNNY DAY” sequence. We use the updated annotations of [121] as used in Caltech evaluation framework [29] but we restrict to those pedestrians taller than 72 pix height. Since, these sequences are only for testing as they do not provide training data, we use the INRIA one as in [29].

The TUD-Brussels Pedestrian dataset [121] acquired from a driving car. It contains motion pairs recorded in busy pedestrian zones from a hand-held camera at a resolution of 720 × 576 pixels. As in [29] we only use the first frame of each motion pair. The training data consists of 1092 images with 1776 annotated pedestrians and 192 negative frames. The test set is recorded with a different camera setting and contains 508 images at a resolution of 640 × 480 pixels with 1326 annotated pedestrians. The dataset is challenging due to the fact that pedestrians appear from multiple viewpoints, at very small scales, many are partially occluded and the fact of the differences in the acquisition settings from training and testing. As before we restrict our evaluation to those pedestrians taller than 72 pix.

CVC02 [49] it is one of our own datasets. It is recorded using a camera based on a CCD color sensor of of 640 × 480 pix resolution, with a lens of 6 mm of focal. The camera is installed in the windshield of a car, forward facing the road. From this dataset we use the classification sequence. The training data is formed by 1016 cropped pedestrians and 154 negatives frames. Additionally, it has 101 positive frames with 581 annotated pedestrians. From the testing set we use 250 positive frames with 1140 annotations and 150 negative frames where 290 pedestrians taller than 72 pixels.

Table 3.3 shows the AMR performance of HOG, LBP and HOG+LBP for TUD, ETH-0,1,2, Caltech and CVC02: 45 detectors that we developed following the same training and evaluation procedure. Figure 3.7 plots the performance curves. For all these experiments we use INRIA training set as done in [29]. Additionally, for the ones that has its own training data, i.e. TUD, CVC02 and Caltech, we also train our models using this data. Thus, these experiments involve 45 train-test runs.

From Table 3.3 we can conclude that for ETH-0,1,2 and TUD datsets the LBP feature does not perform well. Thus, when combining LBP with HOG the results do not improve. This fact is mentioned by the datasets authors [29]. As shown in our
experiments from Table 3.2 the LBP descriptor is very sensitive to changes in the training/testing data. As for ETH-0,1,2 the training data is INRIA and for TUD the training data comes from a different camera setting than the testing data this could cause the problems for the LBP. Besides, for CVC02 and Caltech where the training/testing data comes from the same setting the LBP performs better. This, the HOG+LBP configuration performs the best. From hereinafter we will restrict our ETH-0,1,2 and TUD experiments to HOG features and the CVC02 and Caltech to HOG+LBP. Classifiers trained and tested on the same dataset gives better results than the ones trained on INRIA. This reinforces our intuition that training with datasets of a different nature than the testing ones can produce a performance drop. In Caltech case, either training with INRIA or virtual-world data performs better than using the Caltech case training data. This may suggest that such data lacks variability. However, this is not important for the purpose of this thesis since we can assume that the baseline performance is the one based on INRIA training data as is usually done [29].

3.5.2 Other features

In order to illustrate better the behaviour of training with virtual data versus real one we introduce some extra state-of-the-art descriptors: Haar, EOH and Haar+EOH and a new learning machine: Real-AdaBoost. We follow the experimental settings explained in Sect. 3.2 but introducing some changes in the pedestrian detector.

In particular, for ExtHaar and EOH, we experimentally found that reducing the margin of the canonical window to \( f = 4 \) (almost no context) provides better detection performance. Thus, we discard a part of the background frame for training with ExtHaar/EOH. Note that, technically, the set \( T_{tr}^{I} \) is different for HOG/LBP than for ExtHaar/EOH. However, since the framed pedestrians are the same and only the \( f \) changes, we do not introduce a more complex notation for making explicit such a difference. Analogously for \( T_{D}^{tr} \).

Additionally, we use our Real-AdaBoost implementation. For this study we favor performance instead of processing time, thus, we build a single cascade. Weak classifiers are decision stumps. Following the maximum of random variables rule [102], each weak classifier is chosen from a pool of 300 random 1D descriptors, rather than from all 1D possible descriptors (Table 3.1). By using such a pool, it is warranted that the selected 1D descriptor is better than the 99% of the rest with a probability of 95%. We use accuracy (well classified training samples over the total) as the descriptor selection measurement. From all available ExtHaar and EOH 1D descriptors (Table 3.1) we use only 3,780 for building the strong classifier. We selected such a number because it is the dimension of the HOG descriptor when working with INRIA, which gives good results (Sect. 3.3). In fact, setting such a number is not a solved issue, thus, we did several experiments increasing it. However, we did not obtain significative accuracy improvements, while the training and testing computational time increased a lot.

Table 3.4 summarizes the descriptors parameters of ExtHaar and EOH. Bear in

mind that we also make use of an image-pyramid (in this case using the so-called integral image representation at each level) maintaining fixed the CW size, which is not the traditional procedure [48] but improves the results.

the use of a fixed CW and the pyramidal sliding window procedure, instead of scaling the filters (ExtHaar, EOH). Note that filter scaling is the approach giving rise to the usually reported poor performances (e.g. as in \[29\]). In fact, with our approach, EOH+Haar/Real-AdaBoost is similar in performance to HOG+LBP/Lin-SVM. Of course, scaling the filters turns out in much faster detectors, however, the problem of building fast solutions for pyramidal sliding window is under research \[27\]. Thus, here we have favored better detection.

Fig. 3.8 plots the performance of real-AdaBoost based pedestrian detectors trained on Real and virtual-word data, applied to INRIA and Daimler testing sets. Comparing the performance of the HOG/linear-SVM and the HaarEOH/real-AdaBoost we realize that is almost the same. Moreover, we show the results of three different pedestrian detectors based on different sets of features: Haar/real-AdaBoost, EOH/real-AdaBoost and HaarEOH/real-AdaBoost. The pedestrian detectors trained on the real datasets clearly outperforms their counterparts trained on the virtual-world one. The gap of performance is over 10 points.

### 3.6 Summary

In this chapter we have explored how realistic virtual worlds can help in learning appearance-based models for pedestrian detection in real-world images. Ultimately, this would be a proof of concept of a new framework for obtaining low cost precise annotations of objects, whose visual appearance must be learnt.

In order to automatically collect pedestrians and background samples we rely on
3.6. Summary

players/drivers of a photo-realistic videogame borrowed from the entertainment industry. With such samples we have followed a standard passive-discriminative learning paradigm to train a virtual-world based pedestrian classifier that must operate in images depicting the real world (INRIA, Daimler, ETH-0,1,2, TUD and Caltech). Following such a framework we have tested state-of-the-art pedestrian descriptors (HOG/LBP/HOG+LBP) with Lin-SVM and (ExtHaar/EOH/ExtHaar+EOH) with AdaBoost. Within the same pedestrian detection scheme, we have employed virtual-world based classifiers and real-world based ones (Virtual, INRIA, Daimler, CVC02, ETH-0,1,2, TUD and Caltech). In total 203 train-test runs have been performed to assess detection performance. We have reached the conclusion that both virtual- and real-world based training behave in a similar way. This means that virtual-world based training can provide excellent performance, but it can also produce a performance drop as real-world based training when training and testing comes from somehow different probability distributions. The amount of different pedestrian detectors and datasets allows to take this conclusion as trustworthy. Therefore, we think that the results presented in this chapter are relevant for research in pedestrian detection.
The Land of Painted Caves: Earth’s Children
Jean M. Auel, Book, 2011
Earth’s Children is a series of speculative alternative historical fiction novels written by Jean M. Auel set circa 30,000 years before present. There are six novels in the series. The series is set in Europe during the Upper Paleolithic era, after the date of the first ceramics discovered, but before the last advance of glaciers. The books focus on the period of co-existence between Cro-Magnons and Neanderthals. As a whole, the series is a tale of personal discovery: coming-of-age, invention, cultural complexities, and, beginning with the second book, explicit romantic sex. (Source: Jean M. Auel)

It tells the story of Ayla, an orphaned Cro-Magnon girl that during her childhood she is educated by Neanderthals (the clan), the physical appearance of them corresponds to normal humans for her. However, somehow, she recognizes Cro-Magnons as humans too first time she met them during her youth. Ayla adapts from Neanderthals custom to Cro-Magnons one, keeping the best of both worlds. She is a real survivor in such demanding primitive Earth conditions. Ayla is an icon of robustness and adaptability. Interestingly, Ayla is the Hebrew name for oak tree. It turns out also that there is a popular videogame that incorporates Ayla as character.

In this Thesis we develop a domain adaptation framework inspired in the Ayla character and called V-AYLA. This framework allows to adapt a pedestrian detector trained with virtual-world data to operate in the real world.
Chapter 4

Domain adaptation in virtual- and real-world scenarios

The experiments conducted in previous chapter have shown that virtual-world based training can provide pedestrian classifiers exhibiting high testing accuracy in real world, but they can also report lower accuracy than expected due to dataset shift problem and happens when training and testing data are from a different probability distribution. Thus, it can also appear when the training data comes from real-world images. Accordingly, we have designed a domain adaptation framework, V-AYLA (Fig. 4.1), in which we have tested different techniques to collect a few pedestrian samples from the target domain (real world) and combine them with many examples from the source domain (virtual world) in order to train a domain adapted pedestrian classifier that will operate in the target domain. V-AYLA reports the same detection performance than when training with many human-provided pedestrian annotations and testing with real-world images of the same domain. To the best of our knowledge, this is the first work demonstrating adaptation of virtual and real worlds for developing an appearance-based object detector.

4.1 Introduction

Experiments of Chapt. 3 showed that we obtain the similar performance by training with real-world based samples than by using virtual-world ones, which is encouraging from the viewpoint of object detection in general. However, not only good behavior is shared between virtual- and real-world based training, but some undesired effects too. For instance, let us assume that, for learning a pedestrian classifier, we annotated hundred of pedestrians in images acquired with a given camera. Using such camera and classifier we solve our application. Say that later we shall use a camera with a different sensor or we have to apply the classifier in another similar application/context but not equal. This variation can decrease the performance of our
classifier because the probability distribution of the training data can be now much different than before with respect to the new testing data. This problem is referred to as *dataset shift* [92] and is receiving increasing attention in the Machine Learning field [10, 90, 92] due to its relevance in areas like natural language processing, speech processing, and brain-computer interfaces, to mention a few.

Following the same example, the best we can do is to annotate the images from the new sensor/application/context and learn a new classifier. However, with the aim...
4.2 Domain adaptation framework: V-AYLA

of minimizing the annotation effort, the challenge consists in adapting the trained classifier to the new testing/application domain. Virtual-world images, although photo-realistic, come from a different eye than those acquired with a real camera. Therefore, dataset shift can appear. Thus, our proposal of using virtual worlds to learn pedestrian classifiers we cast in a domain adaptation framework that we call Virtual-AYLA\(^1\), V-AYLA in short, which stands for virtual-world annotations yet learning adaptively (Fig. 4.1). For reaching the desired performance, V-AYLA combines virtual-world samples with a relatively low number of annotated real-world ones, within what we call cool world\(^2\). To the best of our knowledge, this is the first work demonstrating adaptation of virtual and real worlds for developing an appearance-based object detector.

As proof of concept, in this chapter V-AYLA relies on active learning for collecting a few real-world pedestrians, while each original descriptor space as well as the so-called augmented descriptor space will be used as cool worlds. In fact, we will not use the classical sampling within the base-classifier ambiguity region. We borrowed the idea of augmented descriptor space from [90], where it is applied to different problems though no one related to Computer Vision, a field that has largely disregarded dataset shift. Fortunately, this problem has also been explored recently in object recognition [13, 100], although not for a detection task like in this paper. Moreover, in [13, 100] the domains to be adapted are both based on real-world images and the involved descriptors are not the ones used for pedestrian detection.

The remainder of the chapter is organized as follows. Section 4.2 details the domain adaptation technique including the joint domain, the domain exploration and the training. Section 4.3 details the conducted experiments while Sect. 4.4 presents the results and corresponding analysis. Moreover, Sect. 4.5 presents additional experiments in terms of extra datasets and features. Finally, Sect. 4.6 draws the main conclusions.

4.2 Domain adaptation framework: V-AYLA

In one-class discriminative learning, samples \(s \in S\) are randomly collected and an associated label \(y \in \mathcal{Y}\) is assigned to each of them, where \(S\) and \(\mathcal{Y} = \{-1, +1\}\) are the samples and annotation spaces, resp. The set of annotated samples \(T = \{(s_k, y_k) | k: 1 \ldots n\}\) is divided in two disjoint sets, \(T^{tr}\) and \(T^{tt}\), to train and test a classifier.

\(^1\)AYLA evokes the main character, a Cro-Magnon women, of Earth's Children saga by J. M. Auel. Ayla is an icon of robustness and adaptability. During her childhood she is educated by Neanderthals (The Clan), whose physical appearance corresponds to normal humans for her. However, she recognizes Cro-Magnons as humans too the first time she met them. Ayla adapts from Neanderthals to Cro-Magnons customs, keeping the best of both worlds. She is a real survivor in such demanding primitive Earth conditions. Interestingly, Ayla is the Hebrew name for oak tree. It turns out also that there is a popular videogame that incorporates Ayla as character.

\(^2\)Cool world term evokes the film with that title. In it, there is a real and a cool world, in the latter real humans live with cartoons.
C : \mathcal{S} \to \mathcal{Y}, \text{resp.} It is assumed a joint probability distribution \( p(s, y) \) describing our domain of interest \( \delta \). Elements in \( T \) are randomly drawn (i.i.d.) from \( p(s, y) \) and, thus, \( T^{tr} \) and \( T^{tt} \) too. This is the case of settings \( \{T^{tr}_I, T^{tt}_I\} \) and \( \{T^{tr}_D, T^{tt}_D\} \) (Chapt. 3).

In practice, there are cases in which samples in \( T^{tr} \) and \( T^{tt} \) follow different probability distributions. As mentioned in Sect. 4.1, dataset shift is the generic term to summarize the many possible underlying reasons [92]. We claim that the loss of performance seen in Chapt. 3 when using different sets to test and train pedestrian classifiers is due to some form of dataset shift. For instance, this is our assumption for settings \( \{T^{tr}_V, T^{tt}_I\} \) and \( \{T^{tr}_V, T^{tt}_D\} \). Accordingly, in this section we apply domain adaptation to overcome the problem.

In domain adaptation, it is assumed a source domain, \( \delta_s \), and a target domain, \( \delta_t \), with corresponding \( p_s(s, y) \) and \( p_t(s, y) \), which are different yet correlated distributions since otherwise adaptation would be impossible. Annotated samples from \( \delta_s \) are available, as well as samples from \( \delta_t \) that can be either partially annotated or not annotated at all. We focus on the so-called supervised domain adaptation [90], where we have a reasonable number of annotations from \( \delta_s \) and some annotations from \( \delta_t \) too. Since we aim at reducing manual annotations for building object classifiers, our \( \delta_s \) is the virtual world \( \mathcal{V} \), and \( \delta_t \) is the real world \( \mathcal{R} \) (here \( \mathcal{R} \in \{I, D\} \)).

As in Chapt. 3, we assess domain adaptation for HOG and LBP separately, as well as for HOG+LBP using Daimler and INRIA datasets. Also, at the end we perform some experiments with other descriptors (Haar, EOH and Haar+EOH) and other datasets (Caltech, ETH0-1-2, CVC02 and TUD).

### 4.2.1 Virtual- and real-world joint domain

Pedestrian classifiers rely on a descriptor extraction process, \( D \), that transforms the samples, \( s \), into their respective descriptors (i.e. HOG, LBP, etc.), \( x = D(s), x \in \Omega \subset \mathbb{R}^d \). Therefore, the learning process holds in \( \Omega \). In the domain adaptation framework, some \( x \)'s come from \( \delta_s \) samples and others from \( \delta_t \) samples. Thus, it arises the question of how to joint both types of \( x \)'s in order to learn domain adapted classifiers. Since our \( \delta_s \) is based on virtual-world samples and \( \delta_t \) in real-world ones, we call the joint domain cool world. In this paper we test two cases.

The first one, called ORG, comes from just treating virtual- and real-world descriptors equally. In other words, from the learning viewpoint, virtual- and real-world samples are just mixed within the original \( \Omega \).

The second cool world, AUG, is based on the so-called feature augmentation technique proposed in [90]. Instead of working in \( \Omega \), we work in \( \Omega^3 \) by applying the mapping \( \Phi : \Omega \to \Omega^3 \) defined as \( \Phi(x) = \langle x, x, 0 \rangle \) if \( s \in \mathcal{V} \) and \( \Phi(x) = \langle x, 0, x \rangle \) if \( s \in \mathcal{R} \), where \( 0 \) is the null vector in \( \Omega \), and \( x = D(s) \). Under this mapping, \( \langle x, 0, 0 \rangle \) corresponds to a common subspace of \( \Omega^3 \) where virtual and real-world samples (i.e. their descriptors) meet, \( \langle 0, x, 0 \rangle \) is the virtual-world subspace, and \( \langle 0, 0, x \rangle \) the real-world one. The rational is that learning using \( \Phi(x) \) descriptors
4.2 Domain adaptation framework: V-AYLA

instead of $\mathbf{x}$ ones allows the SVM algorithm to jointly exploit the commonalities of $\delta_s$ and $\delta_t$, as well as their differences. We refer to [90] for an explanation in terms of SVM margin maximization.

During training, the full $\Phi(\mathbf{x})$ is used. However, during testing all the samples will come from the real-world (here $I$ or $D$), therefore, only the corresponding option of $\Phi(\mathbf{x})$ is used. Let $\mathbf{w} = < \mathbf{w}_{st}, \mathbf{w}_s, \mathbf{w}_t >$ be the weighting vector learnt by the Lin-SVM algorithm, then during testing we have $\mathbf{w} \cdot \Phi(\mathbf{x}) = \mathbf{w}_{st} \cdot \mathbf{x} + \mathbf{w}_t \cdot \mathbf{x} = \mathbf{x} \cdot (\mathbf{w}_{st} + \mathbf{w}_t) = \mathbf{x} \cdot \hat{\mathbf{w}}$ for $\hat{\mathbf{w}} = \mathbf{w}_{st} + \mathbf{w}_t$. Vector $\hat{\mathbf{w}}$ can be computed once and off-line. Thus, the computational cost and memory requirements for using AUG during testing is the same than the one of ORG.

4.2.2 Real-world domain exploration

Let $n_t^p$ be the maximum number of real-world (target domain) pedestrians a human oracle $O$ is allowed to provide for training. We test four strategies for annotating samples from target domain that $O$ may consider.

Following the first behavior, $O$ annotates $n_t^p$ pedestrians at random (Rnd). The rest of behaviors are based on a sort of selective sampling [23]. In particular, there is a first stage consisting in learning a pedestrian classifier, $C_V$, by using the the virtual-world samples and passive learning. Such a classifier is used in a second stage to ask $O$ for difficult samples from the real-world data. Such samples jointly with the virtual-world ones will be used in a third stage for retraining.

In the second behavior, active learning for pedestrians (Act+), $O$ annotates $n_t^p$ difficult-to-detect pedestrians that correspond with the miss detections. Analogously, we term our third behavior as active learning for background (Act−) because $O$ only marks false positives. While, the idea behind Act− is not to collect the annotated false positives, but the right detections (true positives) as provided by the used pedestrian detector. In other words, in this case, the BB annotations of the $n_t^p$ real-world pedestrians are provided by the pedestrian detector itself. Finally, we term as Act± the fourth behavior since it is a combination of Act+ and Act−. In this case we allow to collect $2n_t^p$ real-world pedestrians because just $n_t^p$ are manually annotated with BBs, which is the task we want to avoid.

Let us define the difficult cases for $C_V$. Given a real-world sample $\mathbf{s}_R$, if $C_V(\mathbf{s}_R) > Thr$, then $\mathbf{s}_R$ is classified as pedestrian. Accordingly, in the Act+ case, $O$ will annotate real-world pedestrians, $\mathbf{s}^+_R$, for which $C_V(\mathbf{s}^+_R) \leq Thr$. In the Act− case, those background samples, $\mathbf{s}^-_R$, for which $C_V(\mathbf{s}^-_R) > Thr$ must be rejected by $O$. For the Act± both things hold. In general, selective sampling for SVM focus on samples inside the ambiguity region $[-1, 1]$. However, underlaying such an approach is the assumption of a shared train and test domain. Here, due to dataset shift, wrongly classified samples out of the margins can be important to achieve domain adaptation.
4.2.3 Training process

Assume the following definitions of training sets:

- **Source domain.** Let \( \mathcal{V}^{tr+} \) be the set of virtual-world images with automatically annotated pedestrians, and \( \mathcal{V}^{tr-} \) the set of pedestrian-free virtual-world images automatically generated as well.

- **Target domain.** Let \( \mathcal{R}^{tr+} \) be a set of real-world images with non-annotated pedestrians, and \( \mathcal{R}^{tr-} \) a set of pedestrian-free real-world images.

Take the following decisions:

- **Classifier basics.** Here we assume Lin-SVM, and \( D \in \{ \text{HOG}, \text{LBP}, \text{HOG+LBP} \} \).

- **Cool world.** Choices are ORG and AUG.

- **Oracle.** Choices are \( O \in \{ \text{Rnd}, \text{Act+}, \text{Act-}, \text{Act±} \} \).

The training method we use for performing domain adaptation can be summarized in the following steps (See Fig. 4.1):

1. **(s1) Perform passive learning in virtual world** using \( \{ \mathcal{V}^{tr+}, \mathcal{V}^{tr-} \} \) and \( D \). Let us term as \( C_V \) the passively learnt pedestrian classifier and as \( D_V \) its associated detector. Let \( T_V^{tr+} \) be the set of pedestrians used for obtaining \( C_V \) (i.e. coming from \( \mathcal{V}^{tr+} \), scaled to the CW size and augmented by mirroring), and \( T_V^{tr-} \) the set of background samples (coming from \( \mathcal{V}^{tr-} \) after bootstrapping, CW size).

2. **(s2) Selective sampling in real world.** In order to obtain real-world annotated pedestrians, we run \( D_V \) on \( \mathcal{R}^{tr+} \) and then apply the \( O \). If \( O = \text{Act±} \), then it collects \( n_p^T \) following Act+ style and \( n_p^T \) more following Act- style (which does not involve manual pedestrian BB annotations). Otherwise, only \( n_p^T \) pedestrians are collected. We term as \( T_R^{tr+} \) the set of such new pedestrian samples scaled to CW size and augmented by mirroring, and as \( T_R^{tr-} \) a set of background samples in CW size, taken from \( \mathcal{R}^{tr-} \) as done in the passive learning procedure before bootstrapping (thus, the cardinality of \( T_R^{tr+} \) and \( T_R^{tr-} \) are equal). Note that to follow \( O \) we need to set \( Thr \). For that purpose, we initially select a few images from \( \mathcal{R}^{tr-} \) and take a \( Thr \) value such that after applying \( D_V \) on the selected images, less than 3 FPPI in average are obtained. We start trying with \( Thr = 1 \) and decrease the value in steps of 0.5 while such a FPPI holds. This is an automatic procedure.

3. **(s3) Perform passive learning in cool world.** Map samples in \( T_V^{tr+}, T_V^{tr-}, T_R^{tr+} \), and \( T_R^{tr-} \) to cool world. Next, train a new classifier with them according to \( D \). Then, perform bootstrapping in \( \mathcal{R}^{tr-} \). Finally, re-train in cool world to obtain the domain adapted classifier.

When \( O \neq \text{Rnd} \), this is a batch active learning procedure [69]. Figure 4.1 summarizes the idea, which, as we introduced in Sect. 4.1, we term as V-AYLA.
4.3 Results

In this section we summarize the V-AYLA experiments (300 training-testing runs in total), and we explain how to simulate the application of V-AYLA on INRIA and Daimler data for providing fair performance comparisons with respect to passive learning. Then, as we have done with the passive experiments, we perform experiments with the most promising techniques on the remaining datasets.

First of all, we shall restrict ourselves to a maximum amount of manually annotated pedestrian BBs from the real-world images (target domain). In the supervised domain adaptation framework, the cardinality of annotated target samples is sup-

posed to be much lower than the one of annotated source samples. However, there is no a general maximum since this depends on the application. As rule of thumb, here we want to avoid the 90% of the manually annotated BBs. In particular, since for both INRIA and Daimler we have used 1,208 annotated pedestrians (i.e. before mirroring) in the passive learning setting, then we will assume the use of a maximum of 120 manually annotated BBs from real-world images. Thus, we aim to achieve the same performance for the following two scenarios: (1) applying passive training using training and testing sets from the same domain, with 1,208 annotated real-world pedestrians; (2) applying domain adaptation with a training set based on our virtual-world data plus a set of 120 real-world manually annotated pedestrians and a set of pedestrian-free images, both sets from the same domain in which we are going to perform the testing.

During an actual application of V-AYLA, the 120 real-world pedestrians used for domain adaptation will change from one training-testing run to another. Thus, this is simulated in the experiments conducted in this section. However, although V-AYLA only needs a few manual BB annotations (i.e. 120 here), our experiments involve 300 training-testing runs, which would turn out in 36,000 manually annotated...
BBs. Therefore, in order to reduce overall manual effort, we have simulated the annotation of the 120 pedestrian BBs by just sampling them from the ones available for the passive learning, according to the different oracle strategies. However, note that during the actual application of V-AYLA all such passively annotated pedestrians (i.e. the 1,208 ones in each considered real-world data set) are not required in advance for further oracle sampling. Our experiments, without losing generality, use such an approach just for avoiding actual human intervention in each of the 300 training-testing runs. Additionally, in this manner the V-AYLA human annotators are the same than the ones of the passive approach, thus, removing variability due to different human expertise.

Hence, in order to simulate V-AYLA on INRIA for $O = \text{Rnd}$, we randomly sample $T_{tr+}^I$ to obtain the 120 real-world pedestrians. For Daimler we do the same using $T_{D}^{tr+}$. For simulating the case $O = \text{Act+}$ on INRIA, we randomly sample the false negatives obtained when applying $C_{V}$ on $T_{tr+}^I$. The desired 120 real-world pedestrians are collected in such a manner. Daimler case is analogous by using $T_{D}^{tr+}$.

$\text{Rnd}$ and $\text{Act+}$ involve manual annotation of pedestrian BBs. However, in $\text{Act−}$ the annotations must be provided by the passively learnt pedestrian detector. INRIA dataset includes the images ($\mathcal{I}_{tr+}^R$) and annotations from which $T_{tr+}^I$ is obtained. Thus, we apply $D_{V}$ to $\mathcal{I}_{tr+}^R$ images, and collect the desired number of pedestrian detections following $\text{Act−}$ behavior. Note that in these experiments $\text{Act+}$ and $\text{Act−}$ take samples from the same original pedestrians in $\mathcal{I}_{tr+}^R$. Once such pedestrians are scaled to the CW size, the difference between those coming from $\text{Act+}$ and $\text{Act−}$ is that, in the former case, the original pedestrians were annotated by a human oracle, while in the latter case it is the own pedestrian detector which annotates them. Simulating $\text{Act−}$ in Daimler is not directly possible since $\mathcal{I}_{tr+}^D$ is not provided, just the corresponding $T_{D}^{tr+}$ is publicly available. In this case, instead of applying $D_{V}$ to $\mathcal{I}_{tr+}^D$, we apply $C_{V}$ to $T_{D}^{tr+}$. Therefore, instead of $\text{Act−}$ we term as $\text{Act∼}$ such an $O$.

For $O = \text{Act±}$, 240 real-world pedestrians are selected. However, only 120 BBs are annotated by a human oracle (Act+), the others are collected according to either Act− for INRIA or Act∼ for Daimler.

In Sect. 4.2.3 we saw that V-AYLA involves finding a threshold value $Thr$. Applying the proposed procedure, we found that $Thr = -0.5$ is a good compromise for all descriptors and real-world data under test.

Table 4.1 shows the application of V-AYLA on INRIA for $O \in \{\text{Rnd, Act+},\text{Act−},\text{Act±}\}$, combined with both ORG and AUG. Regarding Daimler (Table 4.2), we show analogous experiments but replacing $\text{Act−}$ by $\text{Act∼}$, which propagates to $\text{Act±}$. Figure 4.2 plots the curves corresponding to most interesting results.

### 4.4 Discussion

For performing domain adaptation, source and target domains must be correlated, i.e. the passive learning stage of V-AYLA must not give random results, otherwise,
Figure 4.2: Evaluation of domain adaptation. Results for the best cases in Tables 4.1 and 4.2.
the adaptation stage cannot improve them. Fortunately, such a stage of V-AYLA already offers a good approximation as seen in the results of Table 3.2, i.e. virtual-world samples alone help to learn a relatively good pedestrian classifier for real-world images\(^3\). Thanks to that, the adaptation stage of V-AYLA is able to provide state-of-the-art results by just manually annotating a few real-world pedestrian BBs (max. 120). In order to support this statement we have run different statistical tests to compare the results based on just real-world data with the counterparts based on the analyzed domain adaptation techniques. We explain them in the following.

First, we have compared the different cool worlds, i.e. ORG vs AUG. In particular, we use a paired Wilcoxon test considering separately the three descriptors times the four oracles, irrespectively of the real-world testing data set. This turns out in 12 tests. For eight of them AUG is better than ORG, while in the rest there is no statistically meaningful difference. In fact, Tables 4.1 and 4.2 shows that in some cases there are large differences (e.g. for LBP with Daimler) but for the best detectors (i.e. using HOG+LBP) there is not almost performance difference. However, for the sake of reducing the number of remaining statistical tests, in the rest of this subsection we focus on AUG.

Second, we have compared the results of the four oracles using a Friedman test \([44]\). As intuitively expected from the results in Tables 4.1 and 4.2, among oracles Rnd, Act+ and Act± there is no statistically meaningful performance difference. However, Act− outputs worse results thought still improves the performance of using virtual-world data alone. At this point we chose the use of either Act+ or Act± since they have an advantage with respect to Rnd. In particular, it is worth to mention that the pedestrian examples of both INRIA and Daimler datasets where annotated by Computer Vision experts in proprietary software environments, thus, they present good accuracy and variability. Therefore, the Rnd strategy used here is implicitly assuming good annotators. However, this is not always the case when using modern web-based annotation tools \([31, 108]\). We believe, that active strategies (Act+, Act±) have the potential advantage of teaching the human annotator how good quality annotations should be done, since he/she sees the detections output by the current pedestrian detector.

We would like to mention that, although the Act− works worse than the other oracles still is able to provide a step forward in the adaptation (e.g. for INRIA setting more than 5 percentual points with respect to virtual-world based training alone) with the advantage of not requiring manual BB annotations. In fact, Act∼ (i.e. simulated Act−) drives to an analogous performance even though it is based on manual annotations. Note that, in order to do a fair comparison, for respective V-AYLA train-test runs of Act∼ and Act− the same pedestrians are used, only the BB coordinates framing them are different. Therefore, given the potentiality of even reducing more manual annotation we think that the Act− type of oracles (retrained

\(^3\)"She [Ayla] knew they were men, though they were the first men of the Others she could remember seeing. She had not been able to visualize a man, but the moment she saw these two, she recognized why Oda had said men of the Others looked like her." from The valley of the horses (Earth’s Children), J.M. Auel."
for adaptation from self-detections) deserves more research in the future.

Using Wilcoxon unpaired test, we assess if V-AYLA (Act+ and Act±) has achieved domain adaptation, i.e. the null hypothesis is that classifiers trained according to the passive method and V-AYLA exhibit the same performance. In the case of Act+, for HOG V-AYLA is better in 1.12 percentual points with p-value = 0.9097, for LBP it is worse in 1.89 points with p-value = 0.7337, and for HOG+LBP it is better in 0.35 points with p-value = 0.8501. Therefore, we consider that V-AYLA/Act+ has reached domain adaptation. The analogous analysis for Act± concludes that for HOG V-AYLA is better in 1.25 points with p-value = 0.3847, for LBP the same with 1.65 points and p-value = 0.9097, while for HOG+LBP it is worse in 0.50 points with p-value = 0.3847. Thus, again we consider that V-AYLA/Act+ has reached domain adaptation.

In Table 4.3 we summarize the performance improvement obtained when adding the 10% of real-world data to virtual-world one, and viceversa. Note that adding the 10% of real-world data turns out in improvements from 4.5 percentual points to even 10.5 (Δ1). An analogous situation is observed regarding the contribution of the virtual data (Δ2). In the latter case the improvement for HOG (over 8 points for INRIA and Daimler cases) is remarkable since more elaborated models like Latent-SVM part-based ones rely on HOG-style information [36, 37].

In conclusion, V-AYLA allows to significantly save manual annotation effort while providing pedestrian detectors of comparable performance than the obtained by using standard passive training based on a larger amount of manual annotations.

4.5 Additional experiments

For complementing V-AYLA performance assessment, we extend our experiments in two ways: by adding more datasets and by adding more descriptors. To alleviate the number of experiments, as we did in previous chapter, for the remaining experiments we do not repeat the experiments several times. As seen in Table 4.3, classifiers trained with only the 10% of the real data perform clearly worse than our VAYLA ones, so we avoid these experiments with the extra datasets. However, we perform such experiments for the extra features to be sure that this still holds for this features.

4.5.1 Other datasets

We extend our experiments with the extra datasets also used on Chapt. 3: Caltech, ETH-0,1,2, TUD and CVC02. Table 4.4 shows the application of V-AYLA on these datasets. For all of them we adapt the virtual-world data to the INRIA one. Additionally, for the ones that has its own training data, i.e. TUD, CVC02 and Caltech, we also adapt our models using this data. Moreover, we restrict ourselves to just the most promising configurations. Regarding the O we restrict to Rnd and Act±, combined with both ORG and AUG. From results of Fig. 3.7 we decided to use HOG

(*) Adapted to INRIA training set.
(○) Adapted to TUD training set.
(●) Adapted to CVC02 training set.
(♮) Adapted to Caltech training set.

Virtual classifiers adapted to the testing datasets give better results than the ones adapted to INRIA. This reinforces our intuition that training with datasets of a different nature than the testing ones can produce a performance drop.

Table 4.4 reveals that our domain adapted pedestrian detectors outperform the counterpart real based pedestrian detectors (except for CVC02). This emphasises that our methods perform well for a variety of scenarios. Note that the models adapted to its own data are better than the models adapted to INRIA one. Most of the experiments based on models adapted to INRIA with AUG strategy perform better than the ORG ones. This is consistent with the fact that AUG also performed better for the INRIA testing (See Table 4.1). Moreover, the models adapted to its own data following the AUG strategy perform better than the ORG ones. In most of the experiments the Act± oracle leads to better results than the Rand one. For all the datasets except CVC02 the performance given by V-AYLA is superior to the real models. V-AYLA performance clearly improves the virtual one by even 13 points in some cases. In the CVC02 dataset the gap between virtual and real detectors is 25

points that was the only case where V-AYLA could not reach so much adaptation.

4.5.2 Other features

Here we reply our study for the descriptors Haar, EOH and Haar+EOH and the learning machine Real-AdaBoost. Table 4.5 shows the application of V-AYLA on INRIA for \( O \in \{ \text{Rnd}, \text{Act+}, \text{Act−}, \text{Act±} \} \), combined with ORG. Note that AUG a priori can not be applied to AdaBoost. Regarding Daimler (Table 4.6), we show analogous experiments but replacing \( \text{Act−} \) by \( \text{Act~} \), which propagates to \( \text{Act±} \). Figure 4.4 plots the curves corresponding to most interesting results.

Fig. 4.4 shows the AdaBoost based experiments in three different plots: Haar, EOH and Haar+EOH. The plots compare the accuracy of the passive trained classifiers with the domain adapted ones. From these experiments we can draw the following observations:

- Reducing the training data of the target domain to the 10% decreases the performance of any trained detector by more than 10 points of AMR.
Figure 4.4: Evaluation of domain adaptation with other features: Haar and EOH.
4.6. Summary

- All detectors benefit from adding a 10% of random target domain data to the virtual-world set. This benefit varies from 6 to 10 points of AMR.
- Almost all of the tested Act experiments outperform the Rand and target 10% baselines. This is remarkable, since in other contexts it has been shown that the trivial procedure of adding random data performs well and it is usually difficult to outperform. Our proposed active learning procedures clearly outperform the random ones.
- For Haar and EOH Act+ and Act- perform equally but requiring Act- less annotation effort. However, for Haar+EOH Act+ performs better.
- In all the cases Act± outperforms the baselines and the other Act experiments, even slightly outperforming the target trained pedestrian detector for the most important case, the Haar+EOH.

4.6 Summary

In this chapter we have designed a domain adaptation framework, V-AYLA, in which we have tested different techniques to collect a few pedestrian samples from the target domain (real world) and to combine them (cool world) with the many examples of the source domain (virtual world) in order to train a domain adapted pedestrian classifier that will operate in the target domain. Results have shown that following such a framework, as in previous chapter, we have tested state-of-the-art pedestrian descriptors (HOG/LBP/HOG+LBP) with Lin-SVM and (ExtHaar/EOH/ExtHaar+EOH) with AdaBoost. Within the same pedestrian detection scheme, we have employed virtual-world based classifiers and real-world based ones (Virtual, INRIA, Daimler, ETH-0,1,2, TUD and Caltech). Following V-AYLA we have performed 330 train-test runs to assess detection performance. This assessment shows how V-AYLA reaches the same performance than training and testing with real-world images of the same domain.

Altogether, we consider V-AYLA as a new framework from which more research can be done for improving pedestrian detection results (including new features, new models as multi-view/part ones, and ways of building the cool world and collecting samples), propose unsupervised domain adaptation methods as well as to extend the idea to the detection of other objects.
Metropolis
Fritz Lang, film, 1927
Metropolis, a visionary and elaborate spectacle by director Fritz Lang is an epic projection of a futuristic city divided into a working and an elite class. Its exhilarating climax brings the city to its knees, as the classes clash against each other. In the 21st-Century, a de-humanized proletariat labors non-stop in a miserable subterranean city beneath a luxurious city of mile-high skyscrapers, flying automobiles, palatial architectural idylls, tubes and tunnels. With stunningly inventive special effects, Lang’s allegorical narrative and architectural vision creates a highly stylized vision of a not-so-unlikely future (especially for 1926 when the film was made.) As the elite frolic above the clouds, thousands of miserable workers toil night and day inside the belly of the gigantic machine that runs the entire city. Metropolis is controlled by a sinister authoritarian whose son, Freder, rejects his father’s callous philosophy and attitude towards laborers. Meek though they are, the workers are encouraged by Maria, a wistful young woman who wills her comrades to embrace patience and silent strength. Upon discovering her influence upon the workers, a mad scientist kidnaps Maria and creates a robot in her image that will incite the workers to revolt. As Freder races against time to save Maria and curtail the damage done by her doppelganger robot, Metropolis is enveloped in chaos and the classes are brought together in a breathtaking and highly moralistic climax. (Source: Film Affinity)

In this Thesis we aim to reduce the repetitive and boring work of annotating bounding boxes in such a way that this work is done by the machine.
Chapter 5

Reducing human annotation

In this chapter we are interested in other alternatives to the supervised domain adaptation. Ideally, we would like to adapt our system without any human intervention. Thus, a first arising question is: Can the learnt models automatically adapt to changing situations without human intervention? As a proof of concept, we propose the use of unsupervised domain adaptation techniques that avoids human intervention during the adaptation process. We term this system as V-Ayla-U (Fig. 5.1). The last open issue is: How can we avoid the dataset shift without performing domain adaptation? Accordingly, we assess an strategy to collect samples from the real world and train a brand new classifier with them, thus avoiding the dataset shift, but in such a way that no BBs of real-world pedestrians have to be provided. Both proposed methods report the same detection accuracy than when training with many human-provided pedestrian annotations and testing with real-world images of the same domain.

5.1 Introduction

Our ideal goal is to totally avoid human intervention and obtain a system which self-learns how to distinguish objects of interest. Our idea is to remove the oracle of V-Ayla to totally avoid manual labelling. As a first approach, we propose the use of an unsupervised domain adaptation technique. In particular, we explore the use of the transductive SVM (T-SVM) learning algorithm in order to adapt virtual and real worlds for pedestrian detection. We term this system as V-Ayla-U (Fig. 5.1) as it is our unsupervised version of V-Ayla. V-Ayla-U will combine our virtual-world based samples with some real-world based detections to reach the desired performance.

An alternative that we want to explore is the use of the virtual-world data for developing a pedestrian classifier to be used for collecting detections from real-world images. In this first approach, we still require a human oracle that validates the detections as right or false. The idea is that at the end of the process we can obtain a large number of real-world pedestrian BBs without manually annotating them, i.e.
**Figure 5.1:** Unsupervised domain adaptation framework overview. We learn a pedestrian model using automatically labelled virtual-world pedestrians and background. With this model we detect pedestrians in real-world images. Some detections will be true positives and others false ones. Since we do not know which ones are of each type and we do not want human intervention, we treat all them as unlabelled data. Next, such unlabelled samples and the virtual-world labelled ones are joined to train a new pedestrian model using the T-SVM.

the virtual-world-based pedestrian detector provides BBs for us, while the human oracle just provide easy *yes/no*-feedback to validate such BBs. In this work we show that accurate BBs can be obtained through this procedure, saving a lot of oracle time. Moreover, the procedure is adaptable to work in crowd-sourcing style but allowing to propose a simpler task less prone to errors.

Section 5.2 presents the V-AYLA-U and its results. Section 5.3 shows the weakly supervised annotation method and results. Finally, section 5.4 draws the main conclusions.
5.2 Unsupervised domain adaptation

In Sect. 4.2 we applied domain adaptation (DA) to virtual and real worlds, where the former is considered as the so-called source domain and the latter is the target domain. In the DA paradigm it is assumed that we have many labelled samples from the source domain, which in our case are pedestrian and background samples automatically collected (with label) from the virtual world. Regarding the target domain, two main situations are considered: (1) in supervised DA (SDA) we collect a small amount of labelled target-domain data. In Sect. 4.2 we proposed a SDA approach based on active learning. Obtained results, were totally satisfactory in terms of the accuracy of the SDA-based pedestrian detectors. However, the use of active learning implies that a human oracle assists the training. (2) in unsupervised DA (UDA) we collect a large amount of target-domain data but without labels.

Currently we face the last step towards our self-trained pedestrian detector, i.e. we propose not to involve humans annotators/oracles during the training process. In particular in this section we follow an UDA based on transductive SVM (T-SVM) [63]. As we will see in Sect. 5.2.2, for our current image acquisition system, the obtained performance is comparable to the one given by a pedestrian detector based on human assisted training. The conclusions of the presented work are summarized in Sect. 5.2.3

5.2.1 Method

We start our study using the HOG descriptor but replacing the Lin-SVM by Lin-T-SVM (SVM light implementation [62]). If all the provided samples are labelled Lin-T-SVM is equivalent to Lin-SVM, but if not, it unsupervisedly assigns a label to the unlabelled samples.

Now, let us assume the following inputs. First, our source domain: $\mathcal{I}^{tr+}_V$ denotes a set of virtual-world images with automatically labelled pedestrians, and $\mathcal{I}^{tr-}_V$ refers to a set of pedestrian-free virtual-world images automatically generated as well. Second, our target domain: $\mathcal{I}^{tr}_R$ is a set of real-world images without labels. Third, a threshold, $Thr$, such that an image window is said to contain a pedestrian if its classification score is larger than $Thr$. Then, the steps of our UDA are:

(S1) Learning in virtual world with samples from $\{\mathcal{I}^{tr+}_V, \mathcal{I}^{tr-}_V\}$, HOG and Lin-SVM. We term as $C_V$ the learnt classifier and as $D_V$ its associated detector. Let $\mathcal{T}_V^{tr+}$ be the set of pedestrians used for obtaining $C_V$ (i.e. coming from $\mathcal{I}^{tr+}_V$), and $\mathcal{T}_V^{tr-}$ the set of background samples (from $\mathcal{I}^{tr-}_V$). Samples in $\mathcal{T}_V^{tr+}$ and $\mathcal{T}_V^{tr-}$ are assumed to follow standard training steps of pedestrian classifiers, namely, they are in canonical window (CW) size, $\mathcal{T}_V^{tr+}$ includes mirroring, and $\mathcal{T}_V^{tr-}$ includes bootstrapped hard negatives (previous to bootstrapping, we train the initial classifier with the same number of positive and negative samples). Let $C$ denote the current classifier during our learning procedure, and $D$ its associate detector. Now we provide the initialization $C \leftarrow C_V$ (thus, $D$ is $D_V$ at the beginning).
Pedestrian detection in real world. Run D on $\mathbb{I}^{tr}_{R}$: only those candidate windows $W_c$ (provided by the pyramidal sliding window) with $C(W_c) > Thr$ are considered for the final non-maximum suppression stage of the detection process. Some of these detections are true positives, while some others are false ones. We do not know, and treat all them as unlabelled samples. Let us term as $T^{tr?}_{R}$ the set of such detections and their vertically mirrored counterparts down scaled to $CW$ size.

T-SVM learning in cool world with the virtual-world samples (i.e. $T^{tr+}_{V}$ and $T^{tr-}_{V}$) and the real-world unlabelled ones (i.e. $T^{tr?}_{R}$). Figure 5.2 illustrates the underlying idea of the T-SVM training. After this new training we obtain the new $C$ and $D$.

This algorithm can be iterated (with the same or new real-world sequences) by going from (S3) to (S2). However, still we must study the best way of combining unlabelled samples from different iterations to avoid an excessive grow up of the number of samples, which could slow down the T-SVM based training. Although, note that only the HOG of samples of the new iteration must be computed since the ones of previous iterations can be stored. Additionally, some stopping criteria should be provided, which could be based on the similarity of consecutive hyperplanes (classifiers).

5.2.2 Results

Experiments are conducted following the experimental setting explained in Sect. 3.2 and we restrict ourselves to our CVC02 dataset explained in Sect. 3.2.1. Figure 5.3 shows the results of the different experiments we have conducted. Curve CVC-Train-1 refers to the use of a pedestrian classifier trained only with pedestrian and background samples from $\mathbb{I}_{cvc}^{tr}$. Of course, for this experiment the pedestrians in $\mathbb{I}_{cvc}^{tr}$ where manually labelled. Curve Virtual refers to the use of only the virtual-world
5.2. Unsupervised domain adaptation

Figure 5.3: Evaluation of unsupervised domain adaptation: in parenthesis the AMR of the conducted experiments.

data for training. Curves UDA correspond to the results according to the proposed method, i.e. using virtual-world samples and $3_{	ext{rec}}^r$ (without labels) for building the pedestrian classifier. We iterated the learning process three times, the third was not giving any improvement, so we show just two iterations. From one iteration to the next, we preserved all the detections as unlabelled samples. Curves SDA correspond to our Act±approach in Chapt. 4, iterated also until no improvement was achieved, which happens at third iteration too. Note that SDA involves a human oracle during training.

5.2.3 Discussion

From results in Fig. 5.3 we see that Virtual performs worse than CVC-Train-1 (4 AMR points) which we hypothesize is due to dataset shift. When virtual and real world samples are combined, AMR is around 5 points better than CVC-Train-1 and 9 points regarding Virtual, which are large improvements (see typical performance differences among pedestrian detectors in [29]). Iterations pay back in terms of performance improvement (similar to what happens with bootstrapping). Both approaches, SDA and UDA, perform similarly. Thus, we could say that virtual data is complementing well real one. This viewpoint, which applies to both SDA and UDA, corresponds to label real-world samples and use virtual-world ones to complement them. However, note that UDA is able to adapt it for operating in real-world images without human intervention.
Additionally, to complement the study, we trained a pedestrian classifier fully based on manual annotations. More specifically, we labelled 1016 pedestrians in other images taken with our camera and used 150 pedestrian-free images to collect background samples. Then, we trained the classifier following the same procedure that we used for training the classifier only based on virtual-world samples. The curve is shown as \textit{CVC-Train-2} in Fig. 5.3. Note, that it gives better results than our DA approaches (around 2 AMR points), of course, by manually annotating the double of pedestrians than for SDA. However, in the working range from FPPI=1 to FPPI=0.5, UDA (it2) and \textit{CVC-Train-2} shows analogous performance. Now, we can keep improving UDA by showing more sequences to the learning system, while for improving \textit{CVC-Train-2} more manual annotations would be required and it is necessary to follow some sort of active learning procedure (as we do in SDA) to avoid introducing redundant pedestrians.

\textbf{V-AYLA-U} is a great improvement because it removes the human from the adaptation process allowing the system to self adapt to new scenarios. However, T-SVM training is very slow and moreover it requires as parameter an estimation of the ratio positive/negative samples that it is difficult to adjust. So further research is needed in the area of unsupervised domain adaptation.

\section{5.3 Weakly supervised annotation of pedestrian bounding boxes}

In this section propose a \emph{weakly supervised} annotation procedure (See Fig. 5.4), \textit{i.e.} pedestrian BBs are not manually annotated. We first train a pedestrian classifier using only virtual-world data. Then, such a classifier collects pedestrian examples from real-world images by detection. A human oracle rejects false detections through an efficient procedure (See Fig. 5.5). Thus, at the end of the process we obtain pedestrian examples without requiring manual annotation of BBs. Real-world examples are then used to train the final pedestrian classifier. In fact, this procedure is similar to the \textit{oracle Act} but in here we do not retrain with the virtual data and we try to collect as many pedestrian examples as possible. In this way we skip the dataset shift problem without using domain adaptation.

In order to learn pedestrian classifiers we employ the HOG/LinSVM. Under these settings, we show that our weakly supervised approach provides classifiers analogous to their counterparts trained with examples collected by manually annotating the BBs of all the available pedestrians.
5.3. Weakly supervised annotation of pedestrian bounding boxes

5.3.1 Method

Assume the following definitions of training sets:

- **Source domain.** Let $\mathcal{V}^{tr+}$ be the set of available virtual-world images with automatically annotated pedestrians, and $\mathcal{V}^{tr-}$ the set of pedestrian-free virtual-world images automatically generated as well.

- **Target domain.** Let $\mathcal{R}^{tr+}$ be a set of real-world images with non-annotated pedestrians, and $\mathcal{R}^{tr-}$ a set of pedestrian-free real-world images.

Define:

- **Classifier basics, i.e.** pedestrian description process ($\mathcal{D}$, i.e. features computation) and base learner ($\mathcal{L}$).
REDUCING HUMAN ANNOTATION

Figure 5.5: Weakly supervised annotation process. Detections are presented to the oracle ordered by classifier score and in CW size. The oracle marks right detections individually or in groups indicated by initial and final clicks.

- **Detections**, i.e. provide a threshold $Thr$ such that an image window is said to contain a pedestrian if its classification score is greater than $Thr$.

Our weakly supervised training consists of the following steps:

**(s1) Train in virtual world** using $D$ and $L$ with samples from $\{\mathcal{S}_V^{tr+}, \mathcal{S}_V^{tr-}\}$. Let us term as $C_V$ the learned classifier and as $D_V$ its associated detector. Let $\mathcal{T}_V^{tr+}$ be the set of pedestrian examples used for obtaining $C_V$ (i.e. coming from $\mathcal{S}_V^{tr+}$), and $\mathcal{T}_V^{tr-}$ the set of background examples (i.e. coming from $\mathcal{S}_V^{tr-}$). Examples in $\mathcal{T}_V^{tr+}$ and $\mathcal{T}_V^{tr-}$ are assumed to follow standard steps in the training of pedestrian classifiers, namely, they are in canonical window (CW) size, $\mathcal{T}_V^{tr+}$ includes mirroring, and $\mathcal{T}_V^{tr-}$ includes bootstrapped hard negatives (previous to bootstrapping the initial classifier is trained with the same number of positive and negative samples). Let $C$ denote the current classifier during our learning procedure, and $D$ its associate detector. Now we provide the initialization $C \leftarrow C_V$ (thus, $D$ is $D_V$ at the start).

**(s2) Weakly annotating real world.** Run $D$ on $\mathcal{S}_R^{tr+}$. Show the detections to the human oracle ($O$) ordered by $C$ score, and let $O$ to mark the true detections in groups or individually (Fig. 5.5), i.e. like when selecting visual items with a graphical interface of many different modern software applications. Equivalently, we could mark false detections, however, usually true detections are quite far less than false ones. We term as $\mathcal{T}_R^{tr+}$ the set of such new pedestrian examples in CW size and augmented by mirroring. Note that we do not annotate BBs here. This means also that miss detec-
5.3. Weakly supervised annotation of pedestrian bounding boxes

Figure 5.6: Alignment comparison between detections and annotations. Ground truth (top row) and detections (bottom row). Left block of five pedestrians contains detections with classifier score in \([-1, 0)\), those in mid block are in \([0, 1)\), and those in left block correspond to values \(\geq 1\). In our current settings, left and mid blocks are discarded and only the detections of the right block would arrive to the human oracle for validation (along with some hard negatives).

In order to collect hard false negatives we can just take the false detections in \(\mathcal{Z}^{tr+}_{\mathcal{R}}\) (the detections not marked by \(\mathcal{O}\)). However, for an easier comparison of our proposal with the standard learning methods used in pedestrian detection, we run \(\mathcal{D}\) on \(\mathcal{Z}^{tr-}_{\mathcal{R}}\) in order to collect real-world negative samples. Let us term such set of samples as \(\mathcal{T}^{tr-}_{\mathcal{R}}\). Moreover, by doing so it is not necessary to mark all true positives, since not marked detections are not assumed to be false positives.

**(s3) Retrain in real world.** Train a new classifier \(\mathcal{C}\) with the pedestrian examples collected as validated detections, using \(\mathcal{D}\) and \(\mathcal{L}\). The new pedestrian detector \(\mathcal{D}\) is now based just on the new \(\mathcal{C}\).

During step \(s2\), \(\mathcal{D}\) is applied for all images in \(\mathcal{Z}^{tr+}_{\mathcal{R}}\) and \(\mathcal{Z}^{tr-}_{\mathcal{R}}\), then, step \(s3\) is applied once. During \(s2\) we take one negative example per each positive one (same cardinality of \(\mathcal{T}^{tr+}_{\mathcal{R}}\) and \(\mathcal{T}^{tr-}_{\mathcal{R}}\)) and leave for step \(s3\) collecting more hard negatives by training with bootstrapping using the \(\mathcal{Z}^{tr-}_{\mathcal{R}}\) pool.

5.3.2 Experimental settings

We follow the experimental settings proposed on Chapt. 3 but restrict ourselves to HOG/Linear SVM to learn our pedestrian classifiers. For evaluating our weakly supervised annotation proposal, as training real-world dataset we use the INRIA training set. It is worth to note that the BB annotations of the INRIA training and testing sets are considered as precise [108]. We discard the Daimler dataset [32] because it does not have the training frames that are necessary for this work. As in previous chapters, we use the virtual-world dataset from which training the corresponding classifier. For testing, in addition to INRIA testing set, we use: Caltech-Testing (Reasonable
Figure 5.7: Weakly supervision annotation results. Results of detections ('Det' 75%) and corresponding manually annotated BBs ('GT' 75%) from INRIA training set, for different testing sets. 'Real': training with the full INRIA. 'Virtual': training with the virtual-world data.
5.3. Weakly supervised annotation of pedestrian bounding boxes

Figure 5.8: Average miss rate at different testing sets when training with different amounts of validated detections (‘Det’) and corresponding manually annotated groundtruth (‘GT’) from INRIA training set. Each bar shows its average miss rate (%).

set) [29], ETH-0,1,2 and TUD-Brussels [121]. So in total, six testing sets.
In order to perform fair performance comparison among pedestrian classifiers, for any training we need to rely on the same imaged pedestrians. Thus, we only consider those detections whose BB that actually overlap (PASCAL VOC criterion [35]) with some corresponding INRIA training ground truth BB (manually annotated). Thus, paired results termed as 'Det' and 'GT' correspond to pedestrian detectors whose classifiers have been trained with the same pedestrians (INRIA training set), but in one case the BBs of the pedestrians are given by the validated detections ('Det') while in the other such BBs are given by the human oracle ('GT'). Fig. 5.6 compares de 'Det' and 'GT'.

For the experiments presented in Sect. 5.3.3, we also simulate the interaction of the human oracle. In particular, instead of having a person marking the true positives, these are automatically indicated to our system thanks to the training ground truth. This allows to boost the testing of different alternatives at the current stage of our research. However, in Sect. 5.3.3 we evaluate the annotation cost of our proposal by performing some experiments with an actual human oracle in the loop.

Note that we decide if an image window is a detection or not according to the classification score and threshold $Thr$ (Sect. 5.3.1). Here we have set $Thr = -1.0$, i.e. the oracle gives yes/no-feedback for windows with classification score $\geq -1.0$. Note that for SVM classifiers this is in the ambiguity region. Thus, in practice most of the windows presented to the human oracle for yes/no-feedback will be pedestrians, but some of them will be hard negatives.
5.3.3 Results

Figure 5.6 provides visual insight about BB localization accuracy for the detections of the virtual-world-based pedestrian detector applied to the INRIA training set. Figure 5.7 plots the results comparing the performance of the pedestrian detectors resulting from manually annotated BBs vs the BBs resulting from our method (i.e. using validated detections) for the same imaged pedestrians. For sake of completeness, the results of training with both the full INRIA training set and the virtual-world one are plotted as well. Our validated detections reach almost the 80% of the INRIA training pedestrians, so we decided to set 75% as the limit of our method for such a training set. Figure 5.8 plots the average miss rate of the 'Det' and 'GT' pedestrian detectors according to different amounts of training data used, being 75% the maximum.

5.3.4 Discussion

From these results we can draw two main conclusions. On the one hand, the 'Det' and 'GT' performances are so close that we think that BBs from validated detections are as accurate as precise pedestrian BB annotations for developing good classifiers. The difference would be even more negligible by using the HOG/Latent-SVM method for learning deformable part-based models [36], since it is able to refine the annotated BBs provided they are sufficiently precise at the initial stage. On the other hand, the 75% of the annotations seems to already convey the same information than the 100% since the two case give rise to a very similar performance.

In order to quantify the human annotation effort of our weakly supervised method, i.e. in comparison with the human annotation of BBs, we provide Fig. 5.9. Note that annotation time is reduced drastically for the human oracle.

For instance, around only 10 minutes are required to annotate the 75% of the pedestrians (906) since no BBs must be provided. We experimented manual annotation of pedestrian accurate BBs and found an average required time of 6 seconds per BB. Thus, annotating the BBs of the 75% would require 90 minutes (9 times more).

5.4 Summary

In this chapter, we presented V-AYLA-U, our first attempt to extended V-AYLA addressing the challenge of developing a method for obtaining self-trained pedestrian detectors, i.e. without human intervention for labelling samples. For that we have proposed an unsupervised domain adaptation procedure based on T-SVM. In the source domain we have automatically labelled samples coming from a virtual-world, while the target domain correspond to real-world images from which the proposed algorithm selects (by detection) unlabelled samples that correspond to pedestrians and background. Obtained results are comparable to traditional learning procedures where the pedestrians samples are collected by tiresome manual annotation. However,
training a T-SVM is slow and also requires a parameter to be adjusted. Therefore, we leave as an open research line the improvement of V-AYLA-U.

Moreover, we have presented a method for training pedestrian classifiers without manually annotating their required full-body BBs. The two core ingredients are the use of virtual world data, and the design of a weakly supervised procedure to validate detections by yes/no human feedback. Presented results indicate that the obtained classifiers are on par with the ones based on manual annotation of BBs. Besides, the human intervention is highly reduced in terms of both time and difficulty of the annotation task.
Mercedes-Benz E-Class
Mercedes-Benz PRE-SAFE, 2013
Mercedes-Benz has augmented its assistance systems with new functions which are now able to support the driver in a substantially broader range of situations. Using cutting-edge sensor technology, they are able to monitor the area around the vehicle, providing the driver with warnings and support and reducing his workload as an intelligent on-board partner. "Intelligent Drive" is the intelligent combination of sensors and systems to establish a new dimension of motoring. A crucial aspect is the networking of all the systems involved - referred to by safety experts as "sensor fusion". Mercedes-Benz is continually enhancing the capabilities of its assistance systems. The aim is to achieve all-round protection not only for the occupants of a Mercedes-Benz model, but for other road users as well.

Mercedes-Benz PRE-SAFE Brake with Pedestrian Recognition has been evaluated by Mercedes-Benz with the German GIDAS accident data. The evaluation indicates that this new technology could avoid 6 percent of pedestrian accidents and reduce the severity of a further 41 percent.

Chapter 6

Conclusions

In this Thesis we explored the synergies between modern Computer Animation and Computer Vision in order to close the circle: the Computer Animation community has modelled the real world by building increasingly realistic virtual worlds, especially in the field of video games, thus, we learnt our models of interest in such virtual worlds and use them back in real world. Since these models suffered the dataset shift problem we adapted them to operate in the real world. Finally we presented two techniques for reducing the human intervention: an unsupervised domain adaptation procedure and a weakly supervised annotation method. This chapter summarizes the main achievements of our work by revisiting the contributions, strengths and weakness of the proposed methods. Then, we give a perspective of the research line opened with this work. Finally, a brief overview of the future research possibilities in the virtual world generation and domain adaptation techniques are also discussed.

Chapt. 1 introduces the concepts of virtual world and domain adaptation. Here we specified the Thesis scope, the challenge we aimed to achieve and the questions we wanted to answer.

In Chapt. 2 we reviewed the works in the literature more related to ours, namely: pedestrian detection, collecting annotations, engineering examples, and performing domain adaptation.

Chapt. 3 tried to bring light to the following question: Can a pedestrian appearance model learnt with virtual-world data work successfully for pedestrian detection in real-world scenarios? To answer this question we compared the accuracy of our pedestrian detectors trained with virtual world data with the ones trained with real one. The comparison revealed that, although virtual samples were not specially selected, in some cases both virtual- and real-world based training gave rise to classifiers of similar accuracy while there was a gap for others. We realized that this performance drop happens even when training and testing by using real-world data of different origin. To the best of our knowledge there are neither previous proposals for pedestrian detection in particular, nor for object detection in general, where annotations coming
from a photo-realistic virtual world are used to learn an appearance classifier that must operate in the real world. This is the first main contribution of this Thesis. The performance drop that happens when training and testing data from a different nature is known as dataset shift.

In Chapt. 4 we tried to answer the following question: Can we adapt the models learnt in the virtual scenarios to the particularities of the real ones? To answer this question we have designed a domain adaptation framework, V-AYLA, in which we have tested different techniques to collect a few pedestrian samples from the target domain (real world) and combine them with the many examples of the source domain (virtual world). V-AYLA reported the same detection accuracy than the one obtained by training with many human-provided pedestrian annotations and testing with real-world images of the same domain. This gives a positive answer to the posed question. To the best of our knowledge, this is the first work that demonstrates adaptation of virtual and real worlds for developing an appearance-based object detector.

Chapt. 5 further explored other open issues. Ideally, we would like to adapt our system without any human intervention. Accordingly, we asked ourselves Can the learnt models automatically adapt to changing situations without human intervention? To answer this question we doted V-AYLA of an unsupervised domain adaptation technique that avoids human intervention during the adaptation process. We term this system as V-AYLA-U. Our preliminary results served as a proof of concept that gives a positive answer to the question. The last open issue is How can we avoid the dataset shift without performing domain adaptation? Our approach consisted on collecting samples by detection with our virtual world classifier from the real world and train a brand new classifier based only on collected examples, thus avoiding the dataset shift. After, a human oracle rejected the false detections by an efficiently weak annotation. Finally, a new classifier was trained with the accepted detections. We showed that this classifier is competitive with respect to the counterpart trained with samples collected by manually annotating hundreds of pedestrian bounding boxes.

6.1 Future Perspective

Recently several automotive companies have developed their own pedestrian detection systems and started to on-board them in commercial vehicles. Although the technology for developing such systems already exists, the system should work under high performance requirements in any circumstances. To contemplate all these possible scenarios the system has to be trained with an enormous amount of annotated data. Usually, a vehicle fleet is sent to record images during the whole year and this data has to be annotated to train and validate the system. Despite acquiring and analysing this data is very expensive and time consuming, it presents a major challenge: what happen if the system has to work in a different scenario? e.g. changes in the acquisition system, environment, pedestrian cloth style. Then the dataset shift problem may appear and domain adaptation techniques can play an important roll.
to overcome it. Moreover, it arises another question: Could we develop a system that after an initial training it automatically self adapts to new scenarios?

This Thesis is a proof of concept that such systems can self adapt to new scenarios but still further research is required. In the following we point some aspects that require further research.

**Improved virtual worlds:** Video game industry has been blooming since last decade and is one of the economic activities that has not realized about the economic crisis. The realism of the video games in terms of graphics and artificial intelligence is reaching to be completely or almost indistinguishable from reality. However, in this Thesis we used the Half life 2 video game that was created in 2004. So, we expect that using more realistic video games we could achieve better results. In addition, from these games we could acquire ground truth for different applications such as pixel level segmentations for semantic segmentation and scene understanding algorithms, depth information for stereo algorithms, motion for tracking and optical flow algorithms, etc.

**State of the art pedestrian detectors:** In this thesis we focused on holistic pedestrian detectors that are the basis of the state-of-the-art pedestrian detectors such as part-based or patch-based ones. We are already working on extending this work to such detectors as can be seen in the list of our publications.

**Domain Adaptation:** Domain adaptation is a fundamental problem in machine learning but it only started receiving attention in computer vision applications recently. Accordingly, it is a great research opportunity, specially the unsupervised methods.

**Our vision of future ADAS:** We expect that self-trained and self-adapted systems will attract much attention in the next years. These systems will automatically learn new concepts and adapt to new environments cutting down the tedious work of human annotation.

*El trabajo que puede hacer una máquina es inhumano que lo haga una persona*

*The work that can be done by a machine is inhuman to be done by a person*
